BLOOD

The Journal of Hematology

CONTENTS

NOTE Of the twelve issues of BLOOD published in 1948, six were dedicated to Dr George Richards Minot as part of an Anniversary Volume in his honor. These issues, composed of papers by his colleagues, co-workers and former associates (together with a concluding issue to appear in February 1949), are to be collected in volume form early in 1949 as the George R. Minot Symposium on Hematology. The issues dedicated to Dr Minot are indicated in the following Contents by the notation (Minot Anniversary Issue)

No 1

(Minot Anniversary Issue)

Foreword	C Sidney Burwell	5
Treatment of Pernicious Anemia by a Special Diet (A Reprint)	George R. Minot and William P. Murphy	8
Pernicious Anemia from Addison to Folic Acid	Russell L. Haden	22
Twenty Years of Liver Therapy	William P. Murphy	32
Pernicious Anemia, Nutritional Macrocytic Anemia, and Tropical Sprue	Lucy Wells	36
The Relation of Therapy in Pernicious Anemia to Changes in the Nervous System Early and Late Results in a Series of Cases Observed for Periods of not Less than Ten Years, and Early Results of Treatment with Folic Acid	Frank H. Bethell and Cyrus C. Sturges	57
The Development and Progression of Subacute Combined Degeneration of the Spinal Cord in Patients with Pernicious Anemia Treated with Synthetic Pteroylglutamic (Folic) Acid	J. F. Ross, H. Belding and B. L. Paegel	68
Pernicious Anemia Caused by <i>Diphyllobothrium Latum</i> , in the Light of Recent Investigations	Bertel von Bonsdorff	91
Study of the Myelogram (Bone Marrow Puncture) in Pernicious Anemia and the Problem of the Megaloblast	Jacques Mallarmé	103
Refractory Megaloblastic Anemia	L. S. P. Davidson	107
Further Observations on the Specificity of the Folic Acid Molecule	Tom D. Spies, Guillermo Garcia Lopez, Robert E. Stone, Fernando Milanes, Robert O. Brandenburg and Tomas Aramburu	121
Case Report A Case of Pernicious Anemia Requiring Enormous Amounts of Liver Especially by Mouth over Twenty Years	Roger I. Lee	127

No 2

The Schoenlein-Henoch Syndrome of Vascular Purpura	<i>Eli Davis</i>	129
Hyperprothrombinemia Induced by Vitamin K in Human Subjects with Normal Liver Function	<i>Paul N Unger and Shepard Shapiro</i>	137
A Modification of the Waugh-Ruddick Test for Increased Coagulability of the Blood, and Its Application to the Study of Postoperative Cases	<i>Seymour B Silverman</i>	147
In Vitro Study of Bone Marrow III Erythropoiesis In Vitro of Sternal Marrow from Cases of Pernicious Anemia and Lymphatic Leukosis under Therapy	<i>Johannes Clemmesen, Tage Espersen and Claus Munk Plum</i>	155
Studies on Bone Marrow In Vitro III The Effect of Anoxia and Hyperoxia on Explanted Bone Marrow	<i>A Rosin and M Rachmilewitz</i>	165
Electron Microscope Studies of Blood Cells	<i>John W Rebuck and Helen L Woods</i>	175
Case Report Aplastic Anemia, Secondary to Gold Therapy	<i>William J FitzPatrick and Steven O Schwartz</i>	192
Method Spinous Process Puncture A Simple Clinical Approach for Obtaining Bone Marrow	<i>J Philip Loge</i>	198
Adolfo Ferrata (1880-1946)	<i>M Volterra</i>	205
Editorial Marrow Biopsy Technics		209
Abstracts		211
News and Views		223
Book Review		229

No 3

Congenital Hemolytic Jaundice The Pathogenesis of the "Hemolytic Crisis"	<i>Paul A Owren</i>	231
Studies on the Pancytopenia of Kala-Azar	<i>Captain George E Cartwright, Hui-Lan' Chung and An Chang</i>	249
The Effects of Estrogens on the Bone Marrow of Adult Female Dogs	<i>Roger C Crafts</i>	276
The Frequency of Megakaryocytes in Autopsy Sections	<i>Robert Brill and M M Halpern</i>	286
Femoral Bone Marrow Biopsy in the Albino Rat	<i>D G Cameron and G M Watson</i>	292
The Occurrence and Significance of "Motile" Erythrocytes in Human Blood and Marrow in Anemic States	<i>Paul H Ralph</i>	295
Case Report Ulcers of the Leg in Mediterranean Disease	<i>J Earle Estes, Eugene M Farber and J M Stickney</i>	302
Editorial The Hemolytic Crisis		307
Abstracts		309
News and Views		324
Book Review		328

CONTENTS

No 4

(Minor Anniversary Issue)

Clinical Significance of Cardiac and Respiratory Adjustments in Chronic Anemia	<i>Herrman L Blumgart and Mark D Altschule</i>	329
Irreversible Toxic "Inclusion Body" Anemia A Rarely Recognized Syndrome, Clinical and Experimental Studies	<i>M H Fertman and Charles A Doan</i>	349
Blood Response and Nitrogen Balance Following Liver Extract	<i>Randolph West</i>	361
The Pathogenesis of Anemia in Acute Glomerulonephritis Estimations of Blood Production and Blood Destruction in a Case Receiving Massive Transfusions	<i>Charles P Emerson</i>	363
Studies on the Destruction of Red Blood Cells IV Thermal Injury Action of Heat in Causing Increased Spheroidicity, Osmotic and Mechanical Fragilities and Hemolysis of Erythrocytes Observations on the Mechanisms of Destruction of Such Erythrocytes in Dogs and in a Patient with a Fatal Thermal Burn	<i>Thomas Hale Ham, Shu Chu Shen, Eleanor M Fleming and W B Castle</i>	373
The Mechanism of Transplacental Isoimmunization	<i>Philip Levine</i>	404
Erythroblastosis Fetalis in Negroid Infants	<i>A S Wiener and I B Wexler</i>	414
Autohemagglutinins and Hemolysins with Hemoglobinuria and Acute Hemolytic Anemia, in an Illness Resembling Infectious Mononucleosis	<i>Laurence B Ellis, Oscar J Wollenman and Richard P Stetson</i>	419
Primary Nonfamilial Hemolytic Anemia	<i>J M Stickney and Frank J Heck</i>	431
The Genetic Relation and Clinical Differentiation of Cooley's Anemia and Cooley's Trait	<i>Geneva A Daland and Maurice B Strauss</i>	438
Study of Thalassemia Minor in Three Generations of an Italian Family	<i>Robert W Heinle and Margaret Ruth Read</i>	449
Prophylaxis of Hookworm Anemia-Deficiency Disease	<i>W. O Cruz and R Pimenta de Mello</i>	457
A Study of Sickling of Young Erythrocytes in Sickle Cell Anemia	<i>Janet Watson</i>	465

No 5

(Minor Anniversary Issue)

The Chemical Specificity of the Interaction of Diverse Human Plasma Proteins	<i>Edwin J Cohn</i>	471
The Span of Life of the Red Blood Cell	<i>Winifred Ashby</i>	486
Studies on Free Erythrocyte Protoporphyrin, Plasma Iron and Plasma Copper in Normal and Anemic Subjects	<i>G E Cartwright, C M Huguley, Jr, Helen Ashenbrucker, Jane Fay and M M Wintrobe</i>	501
Studies in Iron Transportation and Metabolism VI Absorption of Radioactive Iron in Patients with Fever and with Anemias of Varied Etiology	<i>Reubenia Dubach, Sheila T E Callender and Carl V Moore</i>	526

Osmometric Behavior of Normal and Abnormal Human Erythrocytes	<i>George M Guest</i>	541
A Method for Determining the Form of the Distribution of Red Cell Resistances to Simple Hemolysins	<i>Eric Ponder</i>	556
The Hemoglobin of Healthy College Undergraduates and Comparisons with Various Medical, Social, Physiologic and Other Factors	<i>Clark W Heath</i>	566
Studies of the Staphylocoagulase Reaction Nature and Properties of a Plasma Activator and Inhibitor	<i>Melvin H Kaplan and Wesley W Spink</i>	573
Some Hematologic Effects of Irradiation	<i>William Bloom and Leon O Jacobson</i>	586
The Effect of Radiation on Hemopoiesis Is There an Indirect Effect?	<i>John S Lawrence, William N Valentine and Andrew H Dowdy</i>	593
Normal Blood Counts in Different Seasons	<i>J Engelbreth-Holm and Aa Videbaek</i>	612

No 6

Exogenous Hemochromatosis Resulting from Blood Transfusions	<i>Steven O Schwartz and Sunoll A Blumenthal</i>	617
Histochemical Methods Applied to Hematology	<i>Jack J Rheingold and George B Wislocki</i>	641
Clotting of Plasma and Silicone Surfaces	<i>Thomas B Patton, Arnold G Ware and Walter H Seegers</i>	656
Determination of the Number of Erythrocytes, Volume of Packed Red Cells, Hemoglobin and Other Hematologic Standards in Mexico City (Altitude 7,457 Feet) Study Made on Two Hundred Healthy Persons	<i>Javier Robles Gil and Diego González Terán</i>	660
The Demonstration and Characterization of the Anti-d Agglutinin and Antigen Predicted by Fisher and Race	<i>Sol Haberman, Joseph M Hill, Bruce W Everest and J W Davenport, Jr</i>	682

GEORGE R. MINOT

ANNIVERSARY VOLUME

George R. Mint

A NOTE BY THE COMMITTEE ON THE GEORGE R MINOT ANNIVERSARY VOLUME

Following a testimonial dinner on the occasion of the sixtieth birthday of Dr George R Minot in 1945 a group of his colleagues conceived the idea of the preparation of an Anniversary Volume of manuscripts to be published in honor of Doctor Minot by his colleagues, co-workers, and former associates

A Committee was formed composed of W B Castle, Boston, W Dameshek, Boston (Chairman), R L Haden, Cleveland, E B Krumbhaar, Philadelphia, E Meulengracht, Copenhagen, Denmark, O H Pepper, Philadelphia, R M Suárez Puerto Rico, F H L Taylor, Boston (Secretary), G H Whipple, Rochester, N Y, L J Witts, Oxford, England. Invitations to contribute articles were extended to a world-wide group of active workers in the field of the blood, and to others who had in the past been closely associated with Dr Minot

It appeared eminently desirable that the Anniversary Volume should have full publication in the literature and the Publishers and Editorial Board of BLOOD, *the Journal of Hematology*, graciously opened their pages for the receipt of these manuscripts

The publication of the Anniversary Volume has been made possible by generous gifts from the Lederle Laboratories, Inc, of Pearl River, N Y, and Mr J K Lilly of Eli Lilly and Company, Indianapolis, Indiana. We especially wish to thank Mr Henry M Stratton, our publisher, for his active interest and guidance and for volunteering to underwrite personally the production of the series of articles and of the bound volumes to follow. Our thanks are also due to Dr Henry J Tagnon of the Memorial Hospital, New York, for his aid in the translation of manuscripts

The members of the 'George R Minot Anniversary Volume Committee' deem it a distinct pleasure and a great honor to dedicate these articles by his colleagues and friends to Dr George Richards Minot

A NOTE BY THE EDITORS OF "BLOOD"

The publication of the eighty odd articles in honor of Dr George R Minot will take place in regular issues of BLOOD beginning with the January, 1948 issue, and continuing—probably in alternate issues—throughout 1948. As far as possible, the various articles will be classified and published in groups of related subjects. For example, the first issue deals primarily with pernicious anemia, and the second will deal with miscellaneous problems in anemia.

The Editors have taken the liberty of making notations and minor changes in certain manuscripts, always for the sake of greater clarity. Editorial footnotes are suitably marked, such notes represent the opinions of the Editors and not necessarily those of the authors of the papers. We apologize in advance for any errors that might have crept in, they are unintentional.

WILLIAM DAMESHEK,
For the Editors of *Blood*

FOREWORD

This is a foreword to the series of articles written by his friends and his co-workers to celebrate the achievements of George Richards Minot. It is a good thing thus to give recognition to high scientific accomplishment, it warms the heart of both the donor and the recipient of the recognition, and it reminds other workers that creative thinking is regarded as worthy of praise.

The history and the specific contributions of George Minot are recorded in the bibliography and curriculum vitae which appear on the following pages. Perhaps it is pertinent to inquire what qualities may be associated with this kind of accomplishment.

First of all, George Minot is George Minot, and no one in the world is quite like him. Of course, like almost everyone to whom a "Festschrift" is dedicated, he has been industrious and persistent. He had been surrounded by tradition all his life, and in some ways his reactions and his thinking are highly traditional, but this habit of mind is combined in an extraordinary linkage with an insatiable curiosity and an avidity for understanding that has driven his mind into new and startling regions of thought. That curiosity is a major motive for George Minot is attested by his own writings: "To solve human problems, an active creative imagination and scientific curiosity are necessary tools."

Indeed, the direct desire to explain something otherwise inexplicable may be said to be one of the best motives for research. Its validity in the case of George Minot is shown not only by his own classic discovery of the effectiveness of an adequate dosage of liver in pernicious anaemia, but by his capacity to stimulate curiosity in others, and to gather around himself young men who have curiosity similar to his. The articles to which this note is a foreword make up an adequate example of this side of his character.

To the desire to learn and the desire to encourage curiosity on the part of his students is to be added a great desire to be useful to the sick. If George Minot is to be judged by his motives—a zeal for knowledge, an enthusiasm for teaching, and a humane urge to alleviate suffering and disability—these motives make up a list that lesser personalities may envy.

C. SIDNEY BURWELL, Dean
Harvard Medical School
Boston, Massachusetts

GEORGE RICHARDS MINOT

BIOGRAPHICAL DATA

Born in Boston, Massachusetts, December 2, 1885 Son of James Jackson and Elizabeth (Whitney) Minot

Degrees

A B cum laude	Harvard University	1908
M D cum laude	Harvard University	1912
S D (honorary)	Harvard University	1928

Hospital and University Appointments

Medical House Officer	Massachusetts General Hospital	1912-13
Assistant Resident Physician	Johns Hopkins Hospital	1913-14
Assistant in Medicine and Research		
Fellow, Physiology Laboratory	Johns Hopkins Medical School	1914-15
Assistant in Chemistry	Harvard University	1915-16
Assistant in Medicine	Massachusetts General Hospital	1915-18
Assistant in Medicine	Harvard Medical School	1915-18
Visiting Physician	St Luke's Convalescent Home	1916-18
Assistant Consulting Physician	Collis P. Huntington Memorial Hospital	1917-19
Associate in Medicine	Massachusetts General Hospital	1918-23
Physician	Collis P. Huntington Memorial Hospital	1919-23
Assistant Professor of Medicine	Harvard Medical School	1918-27
Consulting Physician	Massachusetts Charitable Eye and Ear Infirmary	1922-24
Chief of Medical Service	Collis P. Huntington Memorial Hospital	1923-28
Physician to Special Clinic	Massachusetts General Hospital	1923-25
Associate in Medicine	Peter Bent Brigham Hospital	1925-28
Special Consultant in Diseases of the Blood	Massachusetts General Hospital	1925-27
Member Board of Consultation	Massachusetts General Hospital	1927-
Clinical Professor of Medicine	Harvard Medical School	1927-28
Professor of Medicine	Harvard Medical School	1928-
Director, Thorndike Memorial Laboratory	Thorndike Memorial Laboratory Boston City Hospital	1928-
Chief, 4th Medical Service	Boston City Hospital	1928-30
Visiting Physician	Boston City Hospital	1928-

Distinguished Service Award, American Medical Association	1945

TREATMENT OF PERNICIOUS ANEMIA BY A SPECIAL DIET*

By GEORGE R. MINOT, M.D., AND WILLIAM P. MURPHY, M.D.

THIS PAPER concerns the treatment in a series of forty-five cases of pernicious anemia in which the patients were given a special form of diet. While the problem of diet in the treatment of pernicious anemia is by no means new, in our opinion its possible importance has not heretofore been generally recognized. In 1863, seven years after the publication of Addison's second, but best known, description of the disease now called pernicious anemia, Habershon¹ wrote concerning this condition "Many patients at an early stage completely recover under the influence of bracing air and a nutrient and stimulating diet." Other early investigators of the disease, as Biermer² in 1872, and Pepper,³ in 1875, appreciated the desirability of prescribing easily digested foods as a form of medication, but no greater emphasis was placed on the value of diet. Osler,⁴ however, in 1885, mentioned that "cases [of pernicious anemia] appear to have got well with change of air and a better diet after resisting all ordinary means."

During the last half century, many clinicians, following the suggestions of the pioneer writers on the subject of pernicious anemia, have advised various kinds of diet as an aid to induce a remission of the disease. More often than not, the recommendations have been of a general sort as might be given for many persons with an impaired condition of the gastro-intestinal tract, which always is present in pernicious anemia. Thus, food for the pernicious anemia patient often has been selected because it appeared to be easily digested or because it seemed particularly nutritious and strength-giving. Rarely, diets have been chosen for some assumed direct effect on the blood.

The constant presence of achylia gastrica in pernicious anemia and the frequency of an abnormal bacterial activity within the intestines have been two main reasons for establishing certain forms of dietotherapy in the disease. On these accounts, Fenwick,⁵ in 1880, and Naegeli,⁶ among others, recommended diets relatively sparing in farinaceous foods and relatively rich in protein. For similar reasons, yet in contrast to the majority, Hunter,⁷ in 1890, and others have advised quite the opposite type of diet. Grawitz⁸ recommended a diet composed chiefly of fresh vegetables, followed by one with generous amounts of protein. The idea that forced feeding with any sort of food, but especially meats, is valuable to make weak and feeble individuals healthy and strong has caused the frequent use of this form of

From the Medical Clinic of the Peter Bent Brigham Hospital, and the Medical Service of the Collis P. Huntington Memorial Hospital of Harvard University.

This study was aided by a grant from the Proctor Fund of the Harvard Medical School for the Study of Chronic Disease.

* This paper, representing the outstanding contribution of Dr. Minot and Dr. Murphy which won them the Nobel Prize, is reprinted in full from *The Journal of the American Medical Association*, Aug. 14, 1926, Vol. 87, pp. 470-476, by permission of the publishers. Copyright 1926, American Medical Association.

therapy in pernicious anemia, and Mosenthal⁹ has shown that it can restore in these cases a positive nitrogen balance

Meats and green vegetables, partly because of their iron content, have for a long time been thought to be useful to improve 'an anemic state of the blood'. Meat apparently has been chosen at times simply because it contained blood, which was supposed to be beneficial as food for persons who had an insufficient blood supply. The scientific foundations of the value of iron-containing foods to affect the blood-forming organs were laid by Menghini¹⁰ in 1746, when he showed that iron could be increased in the blood by feeding such foods to animals. About 200 years later, Gibson and Howard¹¹ made important observations on the effect of a high iron content of the diet in anemia, and showed that in pernicious anemia it can have a most favorable influence on iron metabolism. They also showed that, in cases constantly losing nitrogen, a positive nitrogen balance could be obtained without forced feeding.

One thus finds that the diet usually advised for the pernicious anemia patient is one containing a relatively high nitrogen-content and often a relatively large number of calories. The recommendations of Smith¹² and of Barker and Sprunt¹³ are of this sort and, like some others, the latter wisely recommend that the food be selected with a view to giving an ordinary, well balanced diet to replace a quantitatively deficient and qualitatively ill balanced one, on which these patients are apt to have placed themselves during their illness.

In spite of attention to diet for the anemic patient, the influence of food on blood formation and destruction has received comparatively little consideration, and special sorts of food, because of some particular effect, have seldom been chosen for patients with pernicious anemia.

Complete starvation in man is not considered to cause anemia, but may do so in animals. However, it is known that improper food can cause, and suitable food alleviate, anemia, for example, the 'iron starvation anemia' arising in infants who have partaken too long of only a milk diet, and who can be cured by food particularly containing complete proteins and iron. Incomplete diets, particularly those low in protein and relatively rich in concentrated carbohydrate food, can lead to anemia,¹⁴ and even Shakespeare¹⁵ recognized that improper food might impair the state of the blood. Likewise, patients with conditions due to, or associated with, vitamin deficiency experience anemia, and Jencks¹⁶ has noticed that an abundance of vitamins favors blood regeneration. Certain foods, including liver, may benefit patients with sprue. This disease is considered by some partly dependent on a faulty diet, and resembles in numerous ways pernicious anemia, including the fact that the blood picture in the two diseases may be quite similar. Carnivorous animals and thin persons tend to have a greater percentage of hemoglobin in their blood than herbivorous animals and fat persons.¹⁷ This further suggests, as do the observations of Morawitz and Kuhl¹⁸ on man, the favorable role that animal protein food may play in blood formation, although dehydration may account for the differences observed.

Some of the earlier experimental work concerning the effect of food on blood

regeneration is reviewed by Pearce, Krumbhaar and Frazier¹⁰ Adequate proteins as well as iron are necessary for the formation of hemoglobin. Certain proteins will not suffice, such as gliadin.²⁰ However, the amino-acid tryptophane may have a special ability to enhance blood formation.²¹ The most important recent work concerning the effect of food on blood regeneration has been done by Whipple and Robschert-Robbins and their associates.²² Their carefully controlled work on dogs has demonstrated clearly the value of certain foods, especially liver, on accelerating blood regeneration following acute hemorrhage and the value of iron added to the diet to decrease the anemia due to chronic blood loss.

McCollum²³ has pointed out that liver and kidneys give an exceptionally high quality protein for a low protein intake and can enhance remarkably the growth of animals. These foods are rich in nucleins, and Calkins, Bullock and Rohdenburg²⁴ have shown that the products of nuclein hydrolysis can stimulate growth. Whipple²⁵ has suggested that in pernicious anemia there may be a scarcity of the material from which the stroma of the red blood cells are formed, or that a disease of the stroma-forming cells of the marrow exists. Thus, theoretically perhaps liver and other foods rich in complete proteins may enhance the formation of red blood cells in this disease, especially by supplying material to build their stroma.

Fresh red marrow was first used as a means of treatment for pernicious anemia by Fraser²⁶ in 1894. He reported beneficial results when a patient ate for some time about 100 Gm. a day. It was then and has since been given apparently on the supposition of some hormone effect. Thus, numerous reports have appeared concerning the use of preparations of small amounts of concentrated bone marrow, but without definite evidence of advantage to the pernicious anemia patient. Reports regarding the effect of eating generously of fresh marrow are few and brief, but suggest that it may be beneficial. The nutritional composition of red bone marrow is similar to that of liver and kidneys. If generous amounts of red marrow and liver can improve the state of the blood in pernicious anemia, may their influence not be due to the same, but unknown, cause?

Various investigators have commented on the blood-destroying properties of certain substances derived from fats, and the rôle they may play in pernicious anemia. Stoeltzner²⁷ recently has reviewed the subject. Also, lipoids have been shown by Baker and Carrel²⁸ to be a factor in serum that can inhibit growth. Thus, founded on somewhat theoretical grounds, it seemed to us, as it did to Stoeltzner²⁷ and to Gibson and Howard,¹¹ that decreasing the amount of fat in the diet of the pernicious anemia patient might have a favorable effect on the state of his blood. Excess of fat in a diet is considered by some to favor putrefaction within the intestine, a condition frequent in pernicious anemia. Hence one might attribute any benefit derived from a low fat content of the diet to alterations in the bacterial flora rather than to some more direct effect on blood formation or destruction.

A further hypothetic reason for decreasing the fat in the diet is that we have noted it is not uncommon for these patients to have consumed throughout life unusually large amounts of food rich in fats. Patients with pernicious anemia also may give a history of partaking for years of some other type of one-sided diet. It is common for them to do so after the definite onset of their illness, when it is not

unusual to find that they have a disgust for meat. Pernicious anemia is rare in certain parts of the world where diets are quite different (containing fewer dairy products, less free sugar and muscle meat) from those of the northern parts of Europe and America, in which areas the disease is relatively common. These different facts permit one to speculate on the possible partial rôle that some nutritional excess or deficiency may play in the etiology of the disease. Similar thoughts have occurred to others, including the idea that a vitamin deficiency might be a causative factor, as has been mentioned, for example, by Elders.²⁹

Leafy vegetables and fruits usually are considered desirable for anemic patients, especially because of their iron content, and strawberries rich in iron appear beneficial for patients with sprue, a disease, as noted, resembling pernicious anemia. We prefer to add these foods to the pernicious anemia patient's diet not only because they are healthful ones for any person to eat, but also because, as Whipple and Robscheit-Robbins³⁰ have shown, certain ones have an especially favorable influence on hemoglobin production. It is quite probable, however, that their chief effect is not because of their iron content. It seems that such a factor as the character of the proteins or amino-acids in the diet is of much more importance than the iron content for pernicious anemia patients.

Numerous authorities hold the view that an intestinal bacterial toxemia plays an important etiologic rôle in this disease. One may choose to believe that any benefit these patients derive soon after beginning to take certain foods is to be attributed to changing rapidly the intestinal flora, thus decreasing a bacterial toxemia, rather than considering that the foods influence in some unknown, but more direct, manner the formation or destruction of red blood cells.

Gibson and Howard,¹¹ taking cognizance of Whipple and Robscheit-Robbins' work and the fact that certain lipid substances could enhance hemolysis, fed pernicious anemia patients a relatively low caloric diet (from 1,500 to 1,900) rich in iron [liver (daily), fruits, green vegetables, egg yolk] and low in fat and adequate in vitamins. A somewhat similar diet but containing a less amount of food rich in purines was recommended by Fenlon³¹ in 1921. Gibson and Howard,¹¹ besides demonstrating the favorable influence of their diet on nitrogen and iron metabolism in pernicious anemia and some other anemias, suggested that it enhanced a remission in pernicious anemia and urged its use.

MATERIAL STUDIED AND OBSERVATIONS

Following the work of Whipple and Robscheit-Robbins, we made a few observations on patients concerning the influence of a diet containing an abundance of liver and muscle meat on blood regeneration. The effect appeared to be quite similar to that which they obtained in dogs. These observations, together with the information given above, led us to investigate the value of a diet with an abundance of food rich in complete proteins and iron—particularly liver—and relatively low in fat, as a means of treatment for pernicious anemia.

Observations set forth below have been made on forty-five patients with typical pernicious anemia first partaking of such a diet when in a relapse and continuing

it to date (except temporarily omitted by three), or from six weeks to two and a half years

The special diet³² used was made as palatable as possible and for each day was practically as follows

- 1 From 120 to 240 Gm , and even sometimes more, of cooked calf s or beef liver An equal quantity of lamb s kidneys was substituted occasionally
- 2 One hundred and twenty grams or more of beef or mutton muscle meat
- 3 Not less than 300 Gm of vegetables containing from 1 to 10 per cent of carbohydrate, especially lettuce and spinach
- 4 From 250 to 500 Gm of fruit, especially peaches, apricots, strawberries, pineapple, oranges and grapefruit
- 5 About 40 Gm of fat derived from butter and cream, allowed in order to make the food attractive However, animal fats and oils were excluded so far as possible
- 6 If desired, an egg and 240 Gm of milk
- 7 In addition to the above mentioned foods, breads especially dry and crusty, potato, and cereals, in order to allow a total intake of between 2,000 and 3,000 calories composed usually of about 340 Gm of carbohydrate, 135 Gm of protein, and not more than 70 Gm of fat Grossly sweet foods were not given, but sugar was allowed very sparingly

This diet is rich in iron and purine derivatives, containing about 0.03 Gm of the former and about 1 Gm of the latter

At the time the diet was advised for many of the patients, they were able to take only a small amount of food of any sort Under these circumstances they were encouraged to take as much as possible of liver and fruits, and at least some vegetables, while other sorts of food were not forced During the first week of the diet, the intake was often less than a thousand calories After about this period of time, the patients usually felt distinctly better and their appetite began to improve Then the food was increased gradually until the complete diet was taken The patients as a rule did so within two weeks after the diet was begun In fact, frequently they soon became "ravenously hungry" and often anxious to eat more than the customary allowance of liver and meat

Twenty-four of the forty-five patients carried out the regimen by weighing portions of liver and meat and estimating the amounts of the rest of their food for at least three weeks, and often for the first six after commencing the diet The other patients, like those after leaving the hospital, have taken their diet at home, following out written directions but not weighing any of their food Our data strongly suggest that the patients who commenced treatment in the hospital and those few able to have a trained nurse at home have improved on the average rather faster and to an even better degree than the others When the patients had remained much better for many weeks, their diet was sometimes modified particularly by decreasing the amount of liver and fruit

The therapeutic regimen for these forty-five patients, besides the special diet, included rest, usually at first in bed for twenty-four hours a day All but three also took each day about 15 cc of diluted hydrochloric acid (U S P) These three, however, improved at least as much as the majority of the others None of the patients received any especial treatment shortly before or after the diet was begun except as follows A man, aged 69, with pronounced spinal cord lesions and ad-

vanced arteriosclerosis, was given five transfusions of blood within about six weeks while attempts were made to get him to eat. Now, three months later, he remains the least well of all forty-five, except for one woman who recently has omitted her diet. Blood was transfused to three others at about the time they first took the special diet. The red blood cell count of none was over 1,400,000 per cubic millimeter four days after transfusion.

The forty-five patients represent an essentially consecutive series seen in a relapse, and are all that have taken the special diet except one noted below. The series is not entirely consecutive, because during the time the forty-five cases were seen the following additional ones came under observation:

1. Four patients who had had their disease a long time were exceedingly sick, able to take little or no food, and died within a few weeks after they were seen. They ate no liver or kidneys.
2. Five patients consulting us but once and not taking the special diet. Letters indicate that three improved somewhat and two did not.
3. One patient that was in much better condition soon after taking the diet. This patient is not included in the series of forty-five because of several unusual complications.

Many of the forty-five patients had had definite symptoms due to pernicious anemia for more than two years, and two of them experienced such symptoms ten years before taking the special diet. A number of the cases were observed during a year or more before the diet was begun, others for several weeks, and some for only a few days. Many of the patients had remained in distinctly poor health and were unable to do their usual work for from a few months to more than a year before eating the food especially prescribed. During this time, many received various forms of therapy without distinct benefit, including transfusions of blood.

When the special diet was started, the forty-five patients that have continued to eat this kind of food fell naturally into the three following groups: (1) twelve in their first distinct relapse, (2) seventeen in their second relapse, (3) sixteen having had two or more relapses. It is thus evident that all sorts of variations of the disease occurred among the patients, and that the series was not composed chiefly of those in their first relapse, following which considerable "spontaneous" improvement is the rule.

The condition of all forty-five patients became much better rather rapidly soon after commencing the diet. All except one, who has recently omitted her diet, are now at the least in a very fair state of health, and if it were not for disorders in some due to spinal cord lesions, would have an appearance to a layman of being essentially well. However, there are only eleven patients who began the diet a year or more ago, two of whom have taken it for more than two years. Eighteen began taking the diet less than five months ago.

One of the earliest signs of improvement has been a change in the frequency of bowel movements believed to be due particularly to the diet and probably not to diluted hydrochloric acid. Within a few days, those who had had a tendency to diarrhea often began to have one formed stool a day, while, interestingly enough, those who had had normal movements or had been constipated frequently had for several days a few loose stools in each twenty-four hours. The latter patients, then, had a more natural regularity of their bowel movements and a more normal stool.

than they had had for some time before the diet was taken. The laxative effect of the diet has been observed also to occur in some normal persons.

Clinical improvement has been obvious usually within two weeks. This has been heralded in the peripheral blood before the end of the first week by the beginning of a most definite rise of the reticulocytes (young red blood corpuscles) of from about 10 per cent to usually about 80 and even to 155 per cent of all the red blood cells. This rise occurred in all fifteen patients that have had such counts made every day or so for from one to three weeks before and some weeks after beginning the diet. By the end of the second week, these cells usually had returned close to their normal percentage. Later, when the red blood cell counts were distinctly high, it

*Average Red Blood Corpuscle Count**

Before diet started		After diet started

* The figures represent the count per cubic millimeter before and after starting special diet in three groups of cases of pernicious anemia (1) with less than 1.2 million, (2) having from 1.2 to 2 million, and (3) having from 2 to 2.75 million before diet was begun. Also, averages for all forty-five cases are shown.

† The differences in the number of cases after about one month is because some have not taken the diet for as long as two, and others as long as four months.

was frequent to find, as we have noted formerly, an abnormally small number of reticulocytes. Before they began to increase, the icterus index of the blood serum in these fifteen patients started to fall, and soon the yellow tint of the patient's skin disappeared. This index reached normal in from two to four weeks, and often has fallen to below normal even when the red blood cell count had increased to only 2,500,000 per cubic millimeter.³³

The accompanying chart and table give in a synopsis manner the trends of the state of the blood in the forty-five patients, taking into consideration, on the one hand, the character of the case, and, on the other, the level of the red blood cells when the diet was begun. The data are given for all forty-five patients before and about one month (from four to six weeks) after the diet was started. Although all the patients have been observed repeatedly, data can be given for only thirty-seven at the end of about two months (from eight to eleven weeks) of treatment, and for twenty-seven between four and six months after treatment began, because eight have taken the diet for less than two months, and eighteen for less than four months. As a measure of the patient's condition, we have chosen to give in the table and chart the red blood cell count rather than the hemoglobin percentage, partly because the latter in pernicious anemia may be at about the same high level

(80 per cent) with red blood cell counts of from 2.5 to 4 million per cubic millimeter. It is recognized that figures for both may vary considerably within a few hours. The figure used in synthesizing the data often represents in each instance an average of several counts made within a few days of each other.

Inspection of the chart and table shows the rapidity with which the red blood corpuscles increased, the high level they attained at the end of about one month, two months and from four to six months after the diet was begun, and the rather slight differences that occurred in the bloods in the cases falling into the three groups based on the number of relapses that had occurred. The percentage increase of cells (and the same is true of the hemoglobin) at the end of a month was usually very

Red blood cell counts in forty-five cases of pernicious anemia before and after beginning special diet. Cases grouped according to the number of relapses the patients had had. One and two months after diet began indicates an approximate amount of time and for any given case is not less and often somewhat more than four or eight weeks. The differences in the total number of cases after about one month are caused by the fact that some patients have had the diet for less than two, and others for less than four, months.

much greater in patients starting the diet when their red blood cell count was less than 1,200,000 per cubic millimeter than in those in whom it was distinctly higher. This occurs in other pernicious anemia patients rapidly restoring their blood. The blood of patients with rather high counts of their red blood corpuscles and prominent signs of injury to the spinal cord responded more slowly perhaps and less well than others, and, as is to be expected, no striking change occurred in very marked symptoms or signs due to spinal cord degeneration.

In pernicious anemia, remissions after two relapses are frequently less marked than previous ones, so that the red blood cell count is apt to be lower in a third or subsequent relapse than in a former one. In spite of the excellent remissions our patients had soon after beginning the diet, the data in the chart show what might

be expected, namely, that not only did the third group of patients (those having had more than two relapses) have on the average a slightly lower red blood cell count before the diet was started, but also that afterward their counts were apt to increase more slowly and not become quite so high as in the other two groups. Only four of the patients had red blood cell counts as low as between 3 and 2.5 million per cubic millimeter after taking the diet for about a month. The cases of three belong to this third group. Even so, two had 4,000,000 or more red blood cells per cubic millimeter at the end of four months. The other, the patient transfused several times, has now, after three months of dieting, only 2,600,000 per cubic millimeter. However, his hemoglobin has risen from 25 to 70 per cent. The fourth case with a red blood cell count of less than 3,000,000 per cubic millimeter at the end of a month belongs to the second group, and now, two and a half months after the diet was started, shows a red blood cell count of 3,300,000 per cubic millimeter.

The data from which the table and chart were prepared have been analyzed in various ways, and the following statements indicate in a different manner than they do what satisfactory improvement was shown in the patients' blood. Seventy-six per cent of all the patients had 2,000,000 or less red blood corpuscles per cubic millimeter, with their hemoglobin usually 55 per cent or less before beginning the diet. In contrast to this, approximately a month (from four to six weeks) later, 91 per cent had over 3,000,000 and 42 per cent over 3,500,000 red blood cells per cubic millimeter, with corresponding rises in the hemoglobin percentage. After taking the diet for about two months (from eight to eleven weeks), 89 per cent (of the 37 that had taken the diet this length of time) had 3,500,000 or more red blood corpuscles per cubic millimeter, while 73 per cent had 4,000,000 or more. All had a hemoglobin of approximately 80 per cent or over. None of the patients studied after they had eaten the food selected for them for between four and six months had less than 3,500,000 red blood cells per cubic millimeter, 81 per cent had 4,000,000 or more, and the counts of 30 per cent were over 5,000,000 per cubic millimeter. The hemoglobin was 80 per cent or above in all, often 90 per cent, and in several cases reached more than 100 per cent. However, it is to be noted that none of these cases observed between four and six months after the diet was started had appeared as advanced as several of those in patients that improved the least, but which have not yet had the diet for four months. The observations on the eighteen patients who have been on the diet for more than six months show that their count may fluctuate, though it has remained above 3,200,000 per cubic millimeter, and usually has been found over 4,000,000, with the hemoglobin remaining 80 per cent or more. There are three exceptions to this statement, for three patients had a relapse about eight weeks after changing their diet. One did so a year and another seven months after the special diet was begun. Both had for two or three weeks a count slightly below 3,000,000 per cubic millimeter. Their red blood cells and hemoglobin then very rapidly increased under rest and on eating an increased amount of liver and fruit. The third patient's red cell count was 4,200,000 per cubic millimeter a month before she changed her diet. She has just resumed the special diet, and her red cell count is 1,900,000 per cubic millimeter and hemoglobin 50 per cent.

COMMENT

Cases of pernicious anemia undergoing distinct remissions often show rapid and striking improvement, such as occurred in almost all our patients. A considerable number of them have made such remarks as, 'I feel better than for several years,' 'better than for two years,' and 'stronger than after the two times my blood went low before.' Such statements, to be sure, are made by pernicious anemia patients having remissions that have not taken this diet, and there is no case in this series of forty-five that cannot be paralleled by a similar one having a so-called spontaneous remission. However, the records of eleven cases show that the red blood cell count in the remission following the 'liver diet' has remained distinctly higher, not only than in a former remission, but also in three cases higher, for at least two months, than in their three previous remissions. It is, thus, again pointed out here that it is rather unusual to find the red blood corpuscle count in a late remission distinctly above the level obtained in several earlier ones. A few of the patients observed for many months before they took the special diet ate, by our advice, relatively small amounts of liver two or three times a week, together with other food of the sort contained in the special diet. Under such a regimen a moderate degree of improvement occurred in some, to be followed later by a relapse of their case. It was rather striking that when the same patients were placed on a diet rich in liver they improved markedly. This suggests, as do similar observations we made some time ago in other cases, that if liver and food like it play a role in improving the blood of pernicious anemia, it is desirable for the patients to take such food daily and in large amounts.

The spontaneous remissions of pernicious anemia and the bizarre course it often runs make it notoriously difficult to determine accurately the effect of any procedure on the disease. All sorts of therapeutic procedures have been advised, many because a few cases improved promptly after their trial. Waves of enthusiasm for certain methods have vanished soon when it was shown that the earlier reports of benefit could be attributed readily to the natural course of the disease. There is, however, no doubt, as shown by some of the early and more recent investigators, that a well balanced, nutritious diet sometimes aids to enhance a remission. The patient may be helped by numerous other forms of treatment, such as those to change the intestinal flora, the injection of protein substances, the taking of arsenic, the transfusion of blood, and splenectomy.

At least one remission, as has been noted by Cabot,³⁴ takes place at some time, but at no regular time, in about 80 per cent of pernicious anemia cases. Precise data are sparse concerning the frequency, degree and rate of remissions in similar groups of cases treated in different ways. Splenectomy has caused quick and marked improvement in 64 per cent of the patients undergoing this operation, while about 15 per cent more have shown some benefit from the procedure.³⁵ However, the remissions that followed have been of no longer duration than those heretofore reported as of a spontaneous nature. Excluding desperately ill patients, Minot and Lee³⁶ noted in 1917 that about 35 per cent of forty patients treated in no especial manner had a moderate or better remission soon after they were seen. Following the transfusion

of blood into forty-six similar patients, about 50 per cent continued to have definitely improved health for at least many weeks than for some time before the procedure. Not more than 20 per cent of the ninety-six patients of these two groups soon had rapid and marked increase in their red blood cells. An analysis of fifty other cases observed between 1916 and 1923 in sequence, except for several in a terminal condition, indicates that 45 per cent developed a definite remission soon after we saw them. These patients were treated in various ways by numerous physicians, but did not eat large amounts of liver or similar food. The remissions were seldom of marked degree, with the red blood corpuscles reaching 4,000,000 or more per cubic millimeter.

No entirely satisfactory data have been found concerning the frequency of remissions following the use of a nutritious high caloric diet and such a regimen as that prescribed by Barker and Sprunt. We have treated in this manner twenty-five partially selected cases, from which it appears that distinct remissions may follow such therapy in about 65 per cent of the instances. Even so, apparently the red blood cell counts of patients on such a diet and who were improved distinctly at the end of one or two months averaged less than for all forty-five who have eaten generously of liver for the same amount of time.

The evidence at hand suggests that the dietetic treatment of pernicious anemia is of considerable importance. It has been possible to demonstrate in forty-five cases seen essentially in sequence that following a diet rich in liver and low in fat a distinct remission of the anemia occurred rather promptly. The promptness and rapidity with which the red blood corpuscles and hemoglobin increased, coincident with at least rather marked subjective improvement in the sense of well being and clinical appearance of all the patients and the strikingly better health of many, is at least unusual in pernicious anemia. It is also not customary for the red blood cell counts during remissions of pernicious anemia to be so frequently of the height that occurred in these patients. We are inclined to believe that something contained in the foods rich in complete proteins is particularly responsible for the improvement in the state of the blood. The low fat content of the diet is assumed to have a less important effect than the character and amount of protein, although probably excess of nitrogen per se is unimportant. If liver and similar food is of value, every means must be taken, including the skill of the nurse and cook, to get patients to eat daily as much as possible, preferably 200 Gm. or more. Failure could be attributed to taking too little of such food.

There are no data to indicate whether the remissions in these forty-five cases will last longer than those of others.

It is possible that this series of cases eventually may be proved to be unusual in that there happened to be treated a group that would have taken a turn for the better under other circumstances. Also, time may show that the special diet used, or liver and similar food, is no more advantageous in the treatment of pernicious anemia than any ordinary nutritious diet. Let this be as it may, at the present time it seems to us, as it has to Gibson and Howard, that it is wise to urge pernicious anemia patients to take a diet of the sort described.

SUMMARY

The dietetic treatment of pernicious anemia is of more importance than hitherto generally recognized

Forty-five patients with pernicious anemia observed essentially in sequence are continuing to take a special diet that they have now been living on for from about six weeks to two years but which was temporarily omitted by three. This diet is composed especially of foods rich in complete proteins and iron—particularly liver—and containing an abundance of fruits and fresh vegetables and relatively low in fat

Following the diet, all the patients showed a prompt, rapid and distinct remission of their anemia, coincident with at least rather marked symptomatic improvement, except for pronounced disorders due to spinal cord degeneration. Improvement was often striking, so that where the red blood cell count averaged for all before starting the diet 1,470,000 per cubic millimeter, one month afterward it averaged 3,400,000, and for the twenty-seven cases observed from four to six months after the diet was begun, the average count was 4,500,000 per cubic millimeter

Patients having had two or more relapses showed on the average slightly lower red blood corpuscle counts about one and two months after commencing the diet than did those who had started it in their first or second relapse

Change in the frequency of bowel movements, temporary increase of reticulocytes in the peripheral blood, and decrease of the icterus index of the blood serum were among the earliest signs that heralded the patient's better health

All the patients have remained to date in a good state of health except three, who discontinued the diet, two rapidly improved on resuming it and the other has just commenced it again. As the diet was advised for most of the patients less than eight months ago, enough time has not yet elapsed to determine whether or not the remissions will last any longer than in other cases

SUBSEQUENT OBSERVATIONS

Since the data presented in this paper were compiled, the following additional information has been obtained. The eight patients who had taken the diet for only about one month had red blood cell counts at the end of about two months of between 3,500,000 and 6,000,000, with an average of 4,400,000 per cubic millimeter. One of these had but 2,500,000 at the end of one month and now at the end of three and a half months has 4,500,000 per cubic millimeter

The ten patients recorded as having taken the diet for only about two months showed in four to six months after starting it as follows. Seven had an average red blood cell count of 5,100,000 per cubic millimeter. One who had had about 5,000,000 had but 3,500,000 per cubic millimeter. Another who had 2,500,000 per cubic millimeter at the end of the second month had the same number two months later, although symptomatically he seemed better. The tenth patient could not obtain the proper diet between the second and fourth month, and had at the latter time 3,000,000 per cubic millimeter

The patients who had the diet from four to six months, or longer, when the data were compiled, continued in the next two and a half months to have on the average as satisfactory counts, except as noted below. The majority of these have shown higher counts than formerly. Two of the cases have had at three different times red blood cell counts of 6,000,000 or more per cubic millimeter. Two patients who have had the diet for more than six months have recently eaten very little liver, and their counts have fallen in two months from about 4,000,000 to about 3,000,000 per cubic millimeter. The red blood corpuscles of the patient referred to on page 16 as in a relapse increased 3,000,000 per cubic millimeter during the first eight weeks after the diet was resumed.

Information at hand suggests that some cases in which transfusion is done many times before the diet is started may respond but little to it.

PERNICIOUS ANEMIA FROM ADDISON TO FOLIC ACID*

By RUSSELL L. HADEN, M D

A CONSTANTLY fatal disease unexplained at autopsy is always intriguing. The mysterious nature of pernicious anemia thus interested Thomas Addison¹ when he described the first group of patients in 1849. He said this is "a remarkable form of anemia which has not attracted the attention it really deserves." The anemia was profound and of unknown origin. The patient became progressively weaker with little wasting and finally died without response to any treatment. A postmortem examination did not aid in explaining the problem. No real progress was made in solving the puzzle until the discovery of the beneficial effect of liver feeding in 1926 by Minot and Murphy² completely altered the outlook of the patient. Further research is slowly unraveling the mystery. Clinicians still think, however, of pernicious anemia as a "remarkable form of anemia."

It is my purpose to discuss historical highlights of this interesting disease from the time of Addison to the discovery of folic acid, and to emphasize some important clinical aspects.

Idiopathic pernicious anemia is a disease of nutrition characterized by macrocytic anemia, histamine-refractory achlorhydria, combined sclerosis of the spinal cord, and a specific response to liver and liver substitutes. The anemia alone may be completely relieved by a single chemical compound, pteroylglutamic acid (folic acid). The clinical picture is variable, the anemia may be minimal, only about three-fourths of the patients have signs of a cord lesion initially, a loss of vibratory sense is usually the earliest and often the only evidence of neurologic involvement, achlorhydria is a constant finding.

It is a disease of older people. In 427 patients studied at the Cleveland Clinic only 5 were less than 30 years of age. In a total number of 579 I have seen, the anemia began in only 1 individual less than 20 years of age. Fifty-two per cent of the patients were between 40 and 60. A very large proportion were over 60 when the diagnosis was made.

Numerous clinicians, beginning with Combe in 1822,³ reported fatal unexplained cases of anemia which we now recognize as pernicious anemia. Thomas Addison, however, first in 1849 and again in 1855⁴ described it as a clinical entity.

Why was the disease so-called? Addison in his original description speaks of it as "a remarkable form of anemia." Its approach is first indicated by a certain amount of languor and restlessness to which presently succeed a manifest paleness of the countenance. The symptoms go on increasing. The patient experiences a distressing and increasing sense of helplessness and faintness. He dies either from sheer exhaustion or death is preceded by signs of passive effusion or cerebral oppression." All patients in this group were not suffering from true pernicious anemia since 2 recovered and in 3, disease of the adrenal was found at autopsy. Addison said in 1855 that he was trying to throw additional light on this

From the Cleveland Clinic, Cleveland, Ohio

* Peter T. Bohan lecture given at the University of Kansas Medical School, March, 1947

condition when he discovered the disease of the adrenal glands known as Addison's disease. He again emphasized that there was no "discoverable cause whatever."

Addison recognized the anemia only by the pallor of the skin and the thinness of the blood. In 1849, no blood cell counts or hemoglobin estimations had been done. Vierordt⁵ did the first red cell count in 1851, Funke⁶ discovered hemoglobin the same year, and Welcher⁷ published the first extensive clinical article reporting blood counts and hemoglobin estimations in numerous diseases in 1854. Thus, accurate measurements of the blood came after Addison's original communication.

Addison's observations made little impression even in England, and little more was heard of this "remarkable anemia" until it was reported independently by Biermer⁸ in Switzerland in 1871. At a meeting of the Medical Society in Zurich, November 6, 1871, Biermer under the title of Progressive Pernicious Anemia described 15 cases of severe anemia. He used the name only in a symptomatic sense, grouping together anemias of widely different etiology. He had previously⁹ mentioned similar cases in which he emphasized fatty degeneration of the heart and vessels. Biermer stressed the role of pregnancy. So some cases he described were evidently what we know now as the anemia of pregnancy. His group has been described as a provisional shelter for a multitude of cases.¹⁰ He did not think of pernicious anemia as a single disease. He again emphasized the finding at autopsy of fatty degeneration of the heart muscle and small vessels.

Biermer's report was published in 1872 in the proceedings of the Medical Society in Zurich. For some unknown reason it quickly excited the interest of clinicians everywhere. Articles on progressive pernicious anemia began to appear rapidly. In England, Addison's original description was not recalled until stimulated by Biermer's work. In 1875, William Pepper¹¹ in Philadelphia wrote an extensive article of 26 pages on the disease in the *American Journal of Medical Sciences*. Pepper says, "My present purpose is to offer a contribution to this important study by calling attention to a peculiar form of anemia of obscure and fatal character which has recently been redescribed (i.e. by Biermer) as though it were a new affection under the name of Progressive Pernicious Anemia." He then emphasizes that Addison had previously described the disease as "idiopathic anemia." Pepper's main contribution is his discovery of the extreme hyperplasia of the marrow. He considered pernicious anemia as a primary disease of the bone marrow.

Many papers on the subject were published between 1875 and 1878. In 1878, Eichhorst's extensive monograph¹² of 375 pages entitled "Progressive Pernicious Anemia" appeared. All cases previously reported were reviewed. Eichhorst mentioned Addison's work but gave him little credit. "Addison," he said, "considered the anemia due to fatty degeneration of the internal organs while we now know that the anemia is primary and the fatty degeneration is secondary." Eichhorst described as pernicious anemia cases of anemia which we now exclude. The term designated only a group of fatal anemias and included such conditions as true aplastic anemia, leukemia, and other bone marrow diseases as well as severe anemias due to infection and toxemia. Eichhorst did not have our present concept of pernicious anemia as a single specific entity. The name he used, however, has persisted. Interest stimulated by these early papers has never abated.

Pernicious anemia is defined as a macrocytic anemia—the red cells are characteristically large. Eichhorst mentions macrocytosis but reports no measurements or even counts in his own cases. He does say the number of red cells was about one-tenth or one-twenty-fifth of normal. The first blood count in a patient with pernicious anemia seems to have been done by Sørensen¹³ in 1874 when he counted the blood with Malassez's apparatus and found only 470,000 red cells. Sørensen also emphasized the large size of the cells. The diameter of red cells had been measured from the time of Leeuwenhoek.¹⁴ A monograph on the dimensions of red blood corpuscles by Manassein¹⁵ had appeared in 1872. Eichhorst concluded that the diameter of the cells is almost always increased.¹⁶ Laache in his book on the anemias¹⁷ published in 1883 has a long discussion of pernicious anemia and emphasizes the large size of the red cells and the increased color index. The decrease in number of red cells, the increase in size, and the increase in hemoglobin content were thus established very early as characteristic findings.

Earlier workers used the red cell diameter as a measure of size. With the development of the hematocrit the cell volume was found increased also and a more sensitive indicator of macrocytosis. Capps,¹⁸ in his work on volume index, found this always increased in pernicious anemia. In our series of 579 patients all showed a macrocytosis if untreated except in the rare instance with a coincident iron deficiency. Other clinical conditions will also produce a macrocytosis but seldom so marked as in a pernicious anemia. Examples are liver disease, intestinal obstruction and nutritional deficiency such as sprue. Ehrlich considered the presence of megaloblasts in the peripheral blood as diagnostic of pernicious anemia. He insisted that these were pathologic nucleated red cells and not simply very young cells. Although Ehrlich and others believed that the diagnosis of pernicious anemia should not be made without the finding of megaloblasts in the blood, this view is no longer held. A diagnosis should never be made of untreated idiopathic pernicious anemia in the absence of a macrocytosis of the red cells.

The presence of an achlorhydria refractory to histamine stimulation is an essential finding. All clinicians now accept the fact that idiopathic pernicious anemia should never be diagnosed if free hydrochloric acid be present on gastric analysis.* The achlorhydria has been a most important factor in the final solution of the origin of the disease. Addison and Biermer knew nothing about achlorhydria.

How did it become recognized that this was a necessary part of the symptom complex? Test meals were not done until relatively late in clinical medicine. Cahn and von Mering¹⁹ first studied the acid in healthy and diseased stomachs in 1886. During the next ten years many articles on the subject appeared in England, on the continent, and in this country. It was soon noted by numerous investigators that when no free hydrochloric acid was found the patients were frequently anemic, and that the anemia belonged in the group already designated as pernicious. As late as 1900, however, Faber and Bloch²⁰ could collect only 33 cases of pernicious anemia on whom a test meal had been done. Martius and von Lubarsch,²¹ in the first monograph on achylia gastrica in 1897, reported both pernicious anemia and

* Wilkinson and Israëls, Waldenström and others report that achlorhydria occurs in approximately 1 case of 100 *EAs*.

secondary anemia associated with achlorhydria. Achlorhydria was not then considered as a necessary part of the clinical picture. The first large group of patients with pernicious anemia on whom test meals had been done were reported by Levine and Ladd²² in 1921. In 107 patients only 3 were found to have free acid. In 2 of these 3 patients the diagnosis was questioned. In the light of present day knowledge all would be questioned. One, for instance, had had several operations and a persistent diarrhea following an intestinal resection. This patient probably had a symptomless obstruction of the small bowel with a macrocytic anemia. Recently Goldhamer,²³ in a report on the gastric acidity during remission in pernicious anemia, mentions 1000 patients at the Simpson Memorial Institute as having had a test meal without finding free hydrochloric acid in a single one. In our series of 579 patients a test meal was done in 546. Free acid was found but once. This patient had a typical clinical and blood picture of pernicious anemia with subacute combined sclerosis. A technical error was not excluded. The test meal was not repeated because the patient died soon after the original examination. No special studies were done to exclude other causes for a macrocytic anemia. Recently we have studied 2 patients with a macrocytic anemia and a normal gastric analysis. Both were found to have a benign chronic intestinal obstruction. These 2 patients also had signs of a subacute combined sclerosis.

A possible relation of the stomach to pernicious anemia through impaired nutrition was recognized long before test meals were done. Immerman¹⁰ in 1877 described pernicious anemia as a disease of nutrition due to faulty absorption of food. Austin Flint²⁴ in 1860 said, "Nor is it difficult to see how fatal anemia must follow an amount of degenerative disease reducing the amount of gastric juice so that the assimilation of food is rendered wholly inadequate to the wants of the body." The English physician, Samuel Fenwick, especially emphasized this point of view. His book, "Atrophy of the Stomach,"²⁵ was published in 1880. Here he recognized severe anemia as occurring with atrophy of the stomach. In Chapter 3 on "The Relation of Gastric Atrophy to Other Forms of Idiopathic Anemia" he remarked that the cases of atrophy of the stomach with anemia reported by him were identical with those described by Addison as idiopathic or pernicious anemia. He quoted Addison's description to emphasize the similarity. Fenwick thought, however, that the anemia was produced by interference with nutrition. He pointed out that the digestive powers of the stomach were so impaired that the usual postmortem digestion solution of the gastric mucosa did not even take place unless acid were added, and the gastric contents would not digest egg albumin. These observations of Fenwick are most important in the light of present knowledge of the relation of the stomach to pernicious anemia. This atrophic condition of the gastric mucosa in pernicious anemia can now be verified in life by gastroscopy.

William Hunter²⁶ long emphasized the relation of the digestive tract to pernicious anemia. He considered the gastric atrophy as resulting from a gastritis due to swallowing bacteria, and the characteristic glossitis to be produced by a specific micro-organism. He believed that a toxin of bacterial origin in the intestinal tract was absorbed into the portal blood and destroyed red cells.

The earlier students of pernicious anemia did not recognize central nervous

system involvement In 1887, Lichtheim²⁷ described 3 patients with severe anemia and involvement of the central nervous system Lichtenstein²⁸ in 1884 had previously described cases of pernicious anemia with findings suggesting tabes dorsalis We now think these patients had pernicious anemia with subacute combined sclerosis In 1892, Minnich²⁹ described 2 patients with pernicious anemia who had serious cord involvement and studied the cord at autopsy He found changes especially in the posterior columns of the spinal cord In this country Dana³⁰ in 1891, in a discussion of degenerative diseases of the spinal cord, described a case with extreme anemia and diarrhea which was evidently pernicious anemia with cord involvement In the same year Putnam³¹ described 8 patients with combined sclerosis which we recognize as having pernicious anemia from the characteristic anemia and other symptoms It is interesting that few of the early observers did blood counts on their patients, so the anemia was evidently quite extreme to be recognized only by pallor or weakness These observers continually emphasized that the nerve involvement is due to poor nutrition resulting from the anemia After 1890, following such early reports numerous articles appeared describing cord lesions In 1902, McGrae³² reported 50 patients with pernicious anemia from the Johns Hopkins Hospital and found neurologic manifestations in 20 of these In 1900, Frank Billings³³ took as his subject for the Shattuck Lecture in Boston, 'The Changes in the Spinal Cord and Medulla in Pernicious Anemia' He emphasized the now well established relation of diffuse cord degeneration and pernicious anemia He thought the anemia and cord changes resulted from a simple toxin which was probably of intestinal origin His article is illustrated with many sections of spinal cord obtained at autopsy

Russell, Batten, and Collier³⁴ in 1900 in discussing subacute combined degeneration of spinal cord described this condition as occurring in patients with severe anemia which was evidently pernicious anemia They thought there was no etiologic relation of the anemia to cord changes In the earlier articles there is necessarily much confusion since the criteria for the diagnosis were not clear Many diagnoses were missed and often cases of severe anemia due to other causes were called pernicious anemia

The central nervous system is affected in 80-85 per cent of cases of true pernicious anemia The most common evidence of cord involvement is a diminution of vibratory sense The cord lesion may be the only significant manifestation of the disease, it may be more serious than the anemia There is no parallel between the degree of anemia and involvement of central nervous system Subacute combined sclerosis may arise from other causes The cord lesions usually respond, at least partially, to liver therapy Sometimes the damage to the central nervous system is beyond repair, so neurologic symptoms and signs may persist when the anemia is entirely relieved

The proof of the relation of the stomach to the origin of pernicious anemia is a most important discovery It is easy to see how the stomach was early incriminated since the anemia had been conceived of as a wasting disease due to impaired nutrition This was well expressed by Austin Flint²⁴ in 1860, as already quoted Immerman's classification of pernicious anemia as a disease of nutrition, and Fenwick's

work, begun in 1871, on gastric atrophy as a cause of anemia, have already been mentioned. Henry and Osler³⁵ in 1886 described a case of pernicious anemia as due to gastric atrophy. Numerous other clinicians made similar reports. Pepper,¹¹ in his very complete article, however, lays no emphasis on changes in the stomach. Then, as gastric analyses were more widely employed, came the discovery that patients with pernicious anemia had an achlorhydria, and finally the conclusion of all clinicians that achlorhydria is invariable in the idiopathic form of the disease. Achlorhydria usually, if not always, precedes the development of the anemia by many years, and persists even in complete remissions. Free hydrochloric acid is not only absent in idiopathic pernicious anemia but the amount of gastric secretion is greatly decreased. Askey³⁶ has recently reviewed 47 cases of pernicious anemia reported as showing free hydrochloric acid on gastric analysis. He emphasized that none can be considered true Addisonian pernicious anemia by present day criteria.

What is the relation of achlorhydria to the causation of pernicious anemia? We are indebted to Castle^{37, 38} for the proof that achylia gastrica is a necessary link in the development of the nutritional deficiency producing the disease. He showed that a patient fails to secrete in the stomach some unknown substance, probably a ferment, which acts on the food to produce a substance or substances necessary for the maturation of the red cells in the bone marrow and for the normal metabolism of nervous tissue. The proof is simple. Ground beef partially digested in the stomach of a normal man with normal gastric secretion when fed to a patient with active pernicious anemia initiates a remission, and causes active blood formation as shown by a rise in reticulocytes and increase in red cells and hemoglobin. Similar preparations exposed to digestion in the stomach of a person with pernicious anemia cause no reticulocytosis or erythrocytosis in other patients suffering from pernicious anemia to whom the material is fed. Such observations proved that a substance supplied by gastric mucosa is a necessary link in the protection against pernicious anemia. It was also shown that the achlorhydria by itself is not a factor but the ferment is never absent if free hydrochloric acid is present. On the other hand the specific ferment may be present if free hydrochloric acid be absent. Castle's work furnished the final proof that pernicious anemia is a deficiency dependent primarily on a gastric defect. Many workers, such as Austin Flint, were right in considering the absence of normal gastric digestion as a cause of anemia though they never thought of such specific action as that demonstrated by Castle. Pernicious anemia may follow total gastrectomy. Meulengracht³⁹ thinks Brunner's glands in the duodenum supply the specific ferment also. If true, this explains normal blood formation after some cases of gastrectomy.

Castle's work disproved other theories of pernicious anemia. Gastrointestinal toxemia, infection, and other possible causes are no longer mentioned. The disease becomes a negative one due to the lack of something, and not a hemolytic one, due to the action of some positive toxic agent.*

The discovery of a specific treatment for pernicious anemia is the most dramatic episode in the long history of this serious disease. Many different methods of

* However, a hemolytic component, causation obscure, is usually present. *Eds*

treatment had been used prior to 1926—iron, hydrochloric acid, arsenic, transfusion, splenectomy, removal of infection, special diets, and drainage of the intestinal tract. At times any method of treatment seemed to produce a remission. Sometimes the effect of transfusion was lifesaving by initiating a remission. No treatment, however, could be depended on to stay permanently the course of the anemia. It was almost always progressive, and usually ended in death from anemia unless some intercurrent fatal disease developed.

In 1920, Whipple⁴⁰ and his associates had begun a systematic study of the effect of different methods of treatment, especially food and drugs, on experimental hemorrhagic anemia in the dog. They found that the most valuable agent in ameliorating the anemia was whole liver. Other foods, such as red meat, had a similar effect to a varying degree but the effect was not so striking as with liver. While Whipple was working with hemorrhagic anemia he emphasized in 1925⁴¹ that "even in complex anemia such as pernicious anemia, anemia with nephritis, and cancer cachexia food factors deserve serious consideration in the clinical management of the blood conditions." Whipple did not apply his discoveries to clinical medicine, however. It remained for Minot and Murphy² to find in a routine trial of liver in various types of anemias, that the response in pernicious anemia was strikingly different from that in other types of anemia. They were helped by the knowledge that the level of reticulocytes is an ideal method of gauging response to treatment. Minot and Murphy's discovery was first announced in 1926 and was rapidly verified by clinicians everywhere.

Liver and liver extracts affect the stroma of erythrocytes only. This verified Whipple's idea expressed in 1922⁴² that there is a scarcity of stroma-building material in pernicious anemia. With adequate liver therapy the blood of a patient about to die rapidly responds and returns completely to normal. The glossitis and other gastrointestinal symptoms disappear entirely. The neurologic symptoms become improved or do not progress, at times they disappear entirely. There is nothing more dramatic in medicine than the effect of liver therapy on a patient with pernicious anemia. Only the use of sulfa drugs and other antibiotics such as penicillin afford such brilliant results.

It was soon found that a liver extract acted just as well as whole liver. Extracts have been improved until now these are almost perfect in their action. A monthly injection of a potent extract will keep the blood normal and prevent the development of a neurologic lesion. An extract of normal gastric mucosa has a similar action as one would expect from Castle's discovery.

Many attempts have been made to isolate from liver and liver extract a single specific substance responsible for the beneficial effect. While highly concentrated preparations have been made no single substance has been isolated. In the meantime, a single chemical substance has been found which gives a specific blood response in pernicious anemia and related macrocytic anemias. Folic acid, a substance found in liver, yeast, spinach, and grasses, has proved to be necessary for the growth of certain bacteria and to relieve the anemia developing in certain vitamin deficient diets. This substance was found to be effective in macrocytic anemias due to a deficiency such as sprue, and other related conditions.

Folic acid is a single chemical compound (pteroylglutamic acid) which causes a specific response also in pernicious anemia. It matures the megaloblasts of the bone marrow so that the blood returns to normal. It probably has little effect on the cord lesion. The latest reports indicate a cord lesion may even develop while the anemia is disappearing and the blood count is normal.

With folic acid the reticulocyte response is not so pronounced as with a potent liver extract but the full effect is excellent and the blood will return to normal. No secondary reticulocytosis occurs in a patient treated with folic acid when liver extract is added. The question is still unsettled whether liver extract and folic acid give a better result than liver extract alone. Folic acid alone should never be used in the treatment of pernicious anemia since it is not the antineuritic factor. It fails to prevent the development or progression of neurologic symptoms indicative of subacute combined sclerosis.⁴³

The anemia of pernicious anemia is due to the lack of a specific red cell maturing factor necessary for the normal development of the erythrocyte. This may well be folic acid since the response of the anemia with adequate amounts of folic acid is complete. The relation of liver extract to folic acid is now being investigated. Liver extract contains small amounts of folic acid but not enough to explain its anti-anemic action. Liver extract has a widespread effect on the individual needing it, possibly through its action on cellular metabolism, as shown by the feeling of well-being exhibited by a person with pernicious anemia after the treatment for a few days with liver extract. The rapid clinical improvement is not due to a relief of the anemia. It has been suggested that liver extract restores normal pteroylglutamic acid metabolism possibly by freeing it from its conjugate form in which it normally occurs in foodstuffs. According to this concept folic acid is related to the blood lesion only. Further research may well show that other specific substances necessary for normal metabolism of nerve tissue are activated by liver extract. Liver extract thus acts as an activator of cellular metabolism⁴⁴ rather than as furnishing specific substances preventing or relieving pernicious anemia. This work suggests that a complex type of cellular enzyme disturbance exists in pernicious anemia. The action of liver principle in restoring normal pteroylglutamic metabolism probably constitutes only one of its therapeutic effects.

SUMMARY

I have tried to review and clarify steps leading to our present knowledge of pernicious anemia as a clinical and etiologic entity. The early history is most illuminating. The development of the present concept of this complicated disease is a triumph of medical research. Many great names both in clinical and research fields are associated with the advance in knowledge of pernicious anemia. Further research will almost certainly clarify problems still unsolved.

TWENTY YEARS OF LIVER THERAPY

By WILLIAM P. MURPHY, M.D.

A PERIOD of slightly more than twenty years has elapsed since the introduction of the use of liver for the treatment of the patient with pernicious anemia. It may be of interest and instructive to consider how well the early predictions in regard to the effects of this treatment have been substantiated and to summarize briefly the progress which has been made during this twenty year period.

The intensive and controlled study of the use of liver in the treatment of pernicious anemia which demonstrated its efficacy and assured its general acceptance was begun in the spring of 1925. The results of these studies as carried out on 45 patients were published in August of the following year.¹ Although diets, some including liver, had been previously tried, it remained for this study to establish liver therapy on a quantitative basis as indicated by the following quotation from this first paper: "If liver and similar food is of value, every means must be taken to get patients to eat daily as much as possible, preferably 200 Gm. or more. Failure could be attributed to taking too little of such food."

At the end of another year and after observation of the effect of therapy in 105 patients, it was possible to predict with greater confidence: "Successful therapy of pernicious anemia depends on the treatment being properly carried out for a correctly diagnosed case. With these conditions established, we believe that essentially all patients with pernicious anemia can be benefited, and usually markedly and promptly."²

Even though the method of treatment has been greatly changed and simplified since the two statements quoted above were written, the predicted beneficial effect of liver (or its extracts) has been confirmed and the advice contained in them relative to treatment has been found to be as important now with the simplified methods of treatment as it was when whole liver was used. Failure to obtain the best results possible are all too frequently the result of the use of insufficient amounts of anti-pernicious anemia substances or to their use only after irreparable damage has been done—too little, too late.

The stages in the progress of treatment from whole liver to an extract of liver for peroral and finally parenteral administration during this twenty year period are so well known that they need not be here repeated. Although several patients have been well maintained for years entirely with the use of whole liver or extracts for peroral use, the treatment of choice for the great majority of patients is with liver extracts for parenteral administration. These extracts are now fairly well standardized and their potency controlled so that the physician has access to highly potent and refined ones which produce a maximal response with a minimum of inconvenience and discomfort to the patient.

The most rapid and in most instances the most satisfactory response to treatment during relapse has been found to follow the injection of large doses of extract

supplying a high content of anti-pernicious anemia substances as elsewhere outlined^{3 4} Thereafter maintenance treatment must be individualized, determined on the basis of its effect on the blood levels and on the neural disturbances if these are present. The amount of liver extract necessary to maintain the best possible state of health varies greatly from one patient to another. The need for adequate therapy cannot be too greatly stressed. In his Nobel lecture made after nearly ten years of experience with liver therapy, Minot⁵ made the following statement: "The grave error in treatment is to prescribe too little liver extract or potent substitute. Where there is doubt, more rather than less should be given. It is essential that the individual receive into his body indefinitely and with regularity enough potent material for his given case." Little need be added to this statement in order to condemn an effort to standardize maintenance therapy. It has been demonstrated that the amount of liver extract needed to maintain a satisfactory state of health as determined from observation of a fairly large group of patients⁶ is that which supplies 15 units about every three and one-half weeks. The actual intervals varied, however, in this group of patients from one to six weeks. It is obvious from this that one cannot produce the best results if the same dose of extract is given to all patients at the same interval.

The more highly concentrated and refined extracts insure the most satisfactory response with the least inconvenience and expense because of the need for less frequent injections. There is no valid argument for the use of so-called 'crude' extracts in the treatment of pernicious anemia even though disturbances resulting from sclerosis of the central nervous system are present. There is much evidence available to confirm the beneficial effect of the concentrated extracts on all of the disturbances characteristic of pernicious anemia including those due to neural damage. No evidence has been presented to show that "crude" extracts are more beneficial in any respect. Furthermore, their use necessitates greater frequency of injection and they are often distinctly more irritating with greater discomfort for the patient. The 'crude' extracts contain a greater amount of solids than do the refined which are probably inert, the content of vitamins and other substances which might add to their value has not been found to be greater and some of those used as 'crude' extracts are merely dilutions of the refined.

The superiority of parenteral extracts over other forms of therapy is in part due to the careful follow-up control of the patient, made possible by his return for injections at regular intervals. The pernicious anemia patient is subject to the same weaknesses of the flesh as are we all. As his condition improves with peroral therapy there is a great temptation to neglect treatment and the check-up visit to his physician, the result in too many instances is hematologic and neurologic relapse. The relatively frequent visits for injection have improved the physician-patient relationship so essential to the most satisfactory control. The importance of this is emphasized by Minot,⁵ also in his Nobel lecture when he cautions: "The physician, however, must do more for his patient than prescribe a proper amount of liver, stomach, or the like, he should attend to all aspects of the case and not neglect attention to the individual's problems of thought and action."

Were it possible for all patients with pernicious anemia to receive treatment

sufficiently early in the course of their disease and in accordance with the principles demonstrated to be most effective, the cause of death would rarely be recorded as that of pernicious anemia. The causes of death have changed somewhat in respect to frequency of occurrence as the average age of the patient has increased in consequence of the liver treatment. Hypertensive cardiovascular disease and malignancy account for a rather high percentage of deaths as might be expected in a control group of comparable age.

The incidence of malignant disease in patients with pernicious anemia is not known. In the author's⁷ series of 578 cases followed during the first twelve years of liver therapy, 29 instances of malignancy involving some part of the body were observed, an incidence of 5 per cent. During that same period malignancy of the stomach caused death in only 4 cases. Two more involving the esophagus were noted. During the twenty year period 50 instances of malignant disease have been observed. Twenty of these involved the stomach and in all but 1, still living, was the cause of death. Whether or not this indicates a higher incidence of gastric carcinoma than occurs in a group of patients of comparable age without pernicious anemia has not been determined. It is quite likely that this is not the case.

The recent synthesis of folic acid⁸ and its demonstrated beneficial effect on the blood levels in pernicious anemia⁹ has stimulated renewed interest in the therapy of the disease. Although this new development may be an important step toward solving several questions concerned with the mode of action of liver or its extracts and although the preliminary reports of its use in the treatment of pernicious anemia are encouraging, it must be remembered that its use is still in the experimental stage. Many of its possible effects are yet to be determined, as for example, the amount necessary to initiate a satisfactory remission during relapse, the amount needed to maintain over a period of years normal blood levels and whether or not that is possible in all patients. Its possible toxic effects are not known and its value in preventing or bringing about improvement of the neural disturbances remains to be seen. Evidence has already appeared to indicate that it does not control these and that it is not a complete substitute for liver or its extracts in the management of pernicious anemia. It is to be hoped that the medical profession will not be stampeded into the use of folic acid as a substitute for liver substances by glowing reports of its value made, particularly in the lay press, by irresponsible writers who do not have at heart the best interests of the patient with pernicious anemia.

Much more study is needed before folic acid can be accepted as a safe and effective substitute for liver and liver extracts. Efforts to side-step a definite decision in this regard by combining folic acid with liver extract merely increase the cost of treatment without definitely adding to its effectiveness. One may confidently say in the light of our present knowledge that liver will do everything that folic acid will do and more for the patient with pernicious anemia.

Finally it may be stated with confidence that results of the use of liver or its extracts in the treatment of pernicious anemia during the twenty years justify the early optimism in regard to its value.

Some of the patients included among the first group of 45 treated and more of

those who were included in the group of 105 reported the following year are alive and well insofar as their pernicious anemia is concerned. Except for the complications which have appeared as the result of increasing age and not related to the anemic state, many more of these original groups would now be living. Few of those who partook of sufficient liver to bring about a satisfactory remission have died from pernicious anemia either as the direct or indirect cause.

Not only have these persons been kept alive but they have been maintained in such good physical condition that it has been possible for them to carry on their normal occupations as housewives, merchants, teachers, lawyers, physicians, etc. The distressing, and often incapacitating, disturbances resulting from damage to the central nervous system have been controlled or completely avoided.

Before the introduction of the liver treatment, the number of deaths from pernicious anemia in the United States alone had risen to about 10,000 per year. It may, therefore, be estimated that 200,000 persons with this disease in this country alone have had their life span increased by at least ten years and that there are 100,000 persons now living with this disease who would not be except for their use of liver or its extracts.

In closing this brief resume of the experiences in the treatment of pernicious anemia with liver and its extracts during this first twenty year period one cannot better express the outlook for the future than did Minot⁵ in the closing words of his Nobel address: "It seems to me that one may expect in the future more information to be obtained which, directly or indirectly, will follow as the result of these observations. Thus, upon the foundations laid by previous investigators, do medical art and science build a structure which will in its turn be the foundation of future knowledge."

PERNICIOUS ANEMIA, NUTRITIONAL MACROCYTIC ANEMIA, AND TROPICAL SPRUE

A DISCUSSION

By LUCY WILLS, M A , M B , B S , M R C S , L R C P

THE BRILLIANT work of Minot and Murphy (1926 and 1927) on the curative action of liver in Addisonian pernicious anemia and the subsequent work of Castle and his colleagues (1929, 1930, 1931, 1936) on the mechanism of the formation of the liver principle opened up a vast field of research into the nature and the mode of action of this principle in pernicious anemia. It was a natural development to extend this field to include a study of other macrocytic megaloblastic anemias and that an explanation of the etiology of all these should be sought on the basis of Castle's theory of an extrinsic-intrinsic factor reaction leading to the formation of the liver principle. Much experimental and clinical work was carried out on these lines, but the concentration on this one aspect of these diseases and recently on the effect of folic acid in the same anemias has, by thus limiting the field, led to a neglect of the study of the general pathology and the natural history of these conditions and perhaps to a too limited view of their etiology. In pernicious anemia, nutritional macrocytic anemia and tropical sprue, to limit the discussion to the three principle macrocytic anemias, anemia is only one aspect of each disease complex and the fundamental differences between the three disease entities have been overlooked in the light of the spectacular success of treatment with liver extracts and folic acid. It was attractive to fit these three diseases, or rather the anemia in each case, into the framework of Castle's theory, according to which all three are due ultimately to a deficiency of the liver principle. Pernicious anemia thus would arise through a deficiency of the liver principle due to an absence from the stomach of the intrinsic factor, nutritional anemia to the same anemia arising from a lack of the extrinsic factor in the diet and the macrocytic anemia of sprue to a failure of absorption of the liver principle, in some cases associated with a reduction or absence of the intrinsic factor. Even had such an explanation in its simple form withstood the test of clinical trials and experimental work, it would not have explained the etiology of the pathologic change in the gastric mucosa in pernicious anemia, to which the absence of the intrinsic factor is attributed, nor that of the functional changes in the intestinal mucosa which lead to the failure of absorption in sprue. This is not to question the validity and applicability of Castle's work, his experimental results belong to the group of "obstinate facts" that have to be reckoned with, but the simple explanation of the causes of the postulated deficiency in 'the liver principle' in these diseases must be revised in view of certain experimental and clinical findings. Undoubted cases of macrocytic anemia due to a deficiency of the extrinsic factor do exist and respond to treatment with this factor (Moore et al , 1944, Watson and Castle, 1946). On the other hand

From the Department of Pathology, Royal Free Hospital School of Medicine, University of London

in many areas where nutritional macrocytic anemia is endemic it has been shown that the anemia does not respond to treatment with purified liver extracts known to be active curatively in pernicious anemia even when these are given in doses equivalent to or much larger than those effective in pernicious anemia. However, in other areas cases have been shown to respond to enormous doses of purified extracts, when the question of traces of other factors possibly present in the extracts has to be considered (for review of literature see Watson and Castle, 1946). Animal experiments have also confirmed the inactivity of highly purified extracts in nutritional macrocytic anemia (Wills et al., 1937) and now modern work on the therapeutic activity of folic acid in macrocytic anemias has to be fitted into the picture.

A consideration of these findings necessitates a reorientation of our mode of approach to the study of these three diseases which does not imply a neglect of the study of the pharmacologic and physiologic action of the elusive liver factor or of that pleasantly concrete substance folic acid. But the approach should be widened to include the natural history of these conditions and a study of their general pathology. In these studies certain considerations should be borne in mind. It should be remembered that the response of the body to any one factor or deficiency varies with the past and present environmental condition, race, family, sex, climate, diet, illnesses, etc., all of which will have determined the physiologic and anatomic state of the body at any one moment of time. The presence or absence of one factor may condition the mode of action of another factor, starving animals on a rachitogenic diet fail to develop rickets. Metabolism proceeds by a series of chain reactions, this is beautifully seen in cellular metabolism where the members of the vitamin B₂ complex play such an important role in the chain of oxidation reduction reactions. The links in these chains may be broken at many points, but the breakdowns thus produced may result in very similar pathologic states. It should also be stressed that a single symptom complex, such as that of a macrocytic hyperchromic anemia may be a part of many different disease entities. Much confusion has arisen for example by the attempt to bring all nutritional macrocytic anemias into one etiological group or to differentiate types on the basis of the serum bilirubin without due consideration of complicating factors. With these considerations in view an attempt will be made to review the natural history and to study the pathogenesis and interrelationships of these three clinical entities. In each case the discussion will be limited to the classic type of each disease, though mention will be made to the large group of ill defined and at present not worked out conditions which have many of the signs and symptoms of the clinical entities under consideration.

GEOGRAPHIC DISTRIBUTION

The distribution of the three diseases varies widely. Pernicious anemia is mainly a disease of the temperate zones, the highest incidence being in the Nordic countries, the British Isles, Canada, and the northern portion of the United States of America. Nutritional macrocytic anemia in its endemic form is, broadly speaking, a disease of tropical and subtropical lands. Originally described as pernicious ane-

mia of pregnancy" in India (Balfour, 1927, McSwcency, 1927, Wills and Mehta, 1930), it was later reported from British Guiana (Giglioli, 1934), East and West Africa, (Trowell, 1943), and probably from Puerto Rico, for though Castle and co-workers (1935) have described the cases of macrocytic anemia they studied there as sprue, it is probable that British workers would consider some, at least, of their cases as nutritional macrocytic anemia Rodriguez-Molina (1939) has described typical cases of nutritional macrocytic anemia from the same island. A similar anemia, which will be discussed later, has been reported from Macedonia by Fairley and his colleagues (Fairley et al, 1938, Foy and Kondi, 1939). Sporadic cases, particularly among pregnant women, have been reported by many workers from Europe and America, but the relation of these cases to the endemic diseases is uncertain. Tropical sprue, as its name implies, occurs mainly in the tropics. It was first described in 1759 by Hillary in the West Indies and then rediscovered in the Far East (Manson, 1879-80), and has since been recognized in many parts of the world. Further, it has long been observed that certain districts and even houses in endemic areas have a high sprue incidence (Leishman, 1945, Keele, 1946).

SEASONAL INCIDENCE

Pernicious anemia is not a seasonal disease. The highest incidence of nutritional macrocytic anemia in Bombay is during the winter months and the lowest during the monsoon (Balfour, 1927). This variation may be related to humidity, temperature or changes in the small additions to the diet, which are of such importance in very deficient and monotonous diets. Marriage customs may also influence the incidence, as they give rise to a seasonal variation in the number of pregnant women in the community and thus to the number of cases of nutritional macrocytic anemia, as this is very prevalent among such women. Hare (1946) reports that in Assam the maximal incidence of anemia, including macrocytic anemia in pregnant women, is in the third quarter of the year, which is the rainy season there. At this time fresh green vegetables are not available and the home pounded rice normally eaten is replaced by milled rice. Napier (1941), in Calcutta found that the highest incidence in pregnant women occurred in the second half of the year, in which, owing to the hot weather and monsoon, less fresh vegetables and fish are taken. The onset of diarrhea in sprue is often associated with the hot weather, when in India the barometric pressure is lowest, but new cases arise at all times of the year.

POPULATIONS AFFECTED

A consideration of the racial and social groups who suffer from these three diseases is of considerable interest as they vary widely. Pernicious anemia appears to be par excellence a disease of people of European descent, particularly of the Nordic races, and is rare in Asiatic or Negro peoples (Friedlander, 1934). Within the racial group affected the disease is no respecter of persons, occurring in men and women of all social strata but showing a marked familial incidence. The individuals affected are characterized by or give a history in other members of the family of a fair complexion and hair and light colored eyes. The other two diseases are, however, class conscious. Endemic nutritional macrocytic anemia occurs in certain ill-

nourished populations, particularly among vegetarians (Taylor and Chhutaní, 1945, Walters, 1947), the poverty-stricken poorer inhabitants of Indian cities (Wills and Mehta, 1930, Mudaliar, 1932, Napier, 1941) the East Indian laborer in Central America (Giglioli, 1934), Indian troops on active service (Marriott, 1945) or the returned Indian prisoner of war (Walters et al, 1947) Pregnant women are especially liable to develop the disease Napier (1941) in Calcutta found that in pregnant women suffering from anemia there is a significant correlation between severe anemia and poverty but that the correlation between macrocytosis and poverty, though very suggestive is not statistically significant His results also suggested a correlation between vegetarianism and macrocytic anemia, but this finding was partly invalidated by the fact of a high positive correlation between vegetarianism and high economic status in the cases studied

Tropical sprue, as originally described by Hillary (1759) in Barbados and as seen in India and the Dutch East Indies is, in contrast, not a disease of the ill-fed native resident, but of the relatively well-fed European or Anglo-Indian resident A distinction must be made here apparently between sprue as originally described and seen typically in India and the Far East, and "sprue as seen in Puerto Rico In India, as mentioned above, the disease affects well-fed Europeans, in Puerto Rico the cases are reported (Castle et al, 1935, Rodriguez-Molina, 1939) as having subsisted for years on a very deficient diet, the intake of good biologic protein being particularly low This is not to imply that in the established syndrome the diet is anything but deficient, for in the untreated cases it most certainly is, the patients limiting their own diets, but the disease originates in well-fed individuals In this respect an outbreak of "acute" sprue that occurred among "the Chindits" in the Burma campaign is of considerable interest These men, picked British troops, existed for weeks on a ration that was only meant for use in a short emergency After a very short time, a matter of days, many of the men developed nausea and vomiting and practically all complete loathing of the ration and in a large proportion of the men the picture of advanced sprue developed in a matter of eight weeks (Keele and Bound, 1946) This history differs markedly from the usual one in a case of sprue and further work is necessary to fit these cases into the sprue picture Many other cases were also reported from East Asia Command by these and other workers

CLINICAL FEATURES

It is not proposed to discuss these in detail but merely to point out the striking differences in the three conditions A long experience of numerous cases of pernicious anemia, nutritional macrocytic anemia and tropical sprue as seen in India, makes it difficult to consider the three conditions as variants of the same disease entity As already mentioned however, it must be borne in mind that the same pathogenic agent produces widely differing clinical pictures in individuals whose genetic makeup varies, who live under diverse conditions of climate, diet, housing, etc, and who have suffered from different stresses and strains all their lives The disease entities may on the other hand be deceptively similar when one particular symptom, for example anemia, dominates the picture Disregarding for the moment

the atypical cases, which may perhaps be the clue to the interrelationship of this group of clinical entities, let us consider typical examples of each disease and compare them one with another

In pernicious anemia the patient usually presents as a well-covered, slightly lemon yellow colored, middle-aged or old individual of European descent, often already showing signs that the nervous system is involved. Very different is the picture in nutritional macrocytic anemia. The age of the patient varies from the late teens to relative old age, in India I never saw a case in a young child, but Giglioli (1934) reports 6 cases out of 51 cases below the age of 12 years, the youngest being 11 months old. The patient is commonly emaciated but in British Guiana, Macedonia and Calcutta, all areas where this anemia occurs in a population which has a high malaria rate, emaciation is not such a marked feature. Some degree of edema is common as in all severe anemias but it is sometimes extreme, occasionally from associated beri beri or hunger edema. As far as a dark skin will permit one to judge, the patient is not jaundiced, has clear conjunctivae and, with the exception of the prisoners of war, has no signs of associated disease of the central nervous system. In Bombay, where the nutritional anemia is extremely common, an occasional case may be frankly jaundiced but nearly always this was found to be associated with syphilis or malaria. In highly malarious areas such jaundiced cases are frequent. The sprue case, generally of European descent and frequently a middle-aged individual, is emaciated but with a distended abdomen often with visible peristalsis, the skin is greyish or a dirty yellow color. The signs and symptoms of other deficiencies such as tetany or purpuric manifestations may be present.

One sign which, together with the anemia, has been taken to indicate a close relationship between these conditions is diarrhea. This may occur in pernicious anemia, but is not a very constant finding and is often controlled by hydrochloric acid alone. In nutritional macrocytic anemia the occurrence of diarrhea is of considerable interest. In certain years in Bombay it was not a common complication though severe cases of nutritional macrocytic anemia occurred, in other years it was noted that diarrhea, often associated with a typhoid or hectic temperature which led to the isolation of the patient, was a very frequent complication. No specific organism could be isolated from the stool and the whole syndrome cleared on marmite or a crude liver extract and did not tend to relapse (Wills, unpublished). Giglioli (1934) reported diarrhea in only a few cases, whereas Napier (1941) reported a significant positive correlation between macrocytic anemia and diarrhea, an incidence of 42 per cent in 45 pregnant cases. A very similar sequence of events is seen in monkeys rendered anemic by faulty feeding, the anemia which is apparently the counterpart of the human condition might develop to an extreme degree without intestinal symptoms appearing or another time it might be associated with severe diarrhea which, with the anemia, improved immediately, as in the human cases, on treatment with active preparations of liver or yeast. In the animal cases too no specific organism could be isolated from the stools (Wills, unpublished). In returned Indian prisoners of war with a high incidence of nutritional macrocytic anemia, diarrhea was rarely complained of and was present in only 5 per cent of those requiring hospital treatment (Walters et al, 1947). In sprue,

which commonly develops insidiously but may develop suddenly, sore tongue and diarrhea dominate the clinical picture. The type of stool is characteristically bulky, greasy, frothy and pale, differing from that seen in the diarrhea complicating nutritional macrocytic anemia of men and monkeys, where it is usually more watery and neither so pale or so frothy. But atypical enteric stools may occur in the acute phases of sprue. The sore tongue, which also occurs in pernicious anemia and nutritional macrocytic anemia is a far more constant feature in sprue.

Nervous lesions other than signs of neuritis are lacking in both nutritional macrocytic anemia and tropical sprue. In Bombay in several hundred cases signs or symptoms of subacute combined degeneration were absent and Fairley (1936) reports the same absence in 450 cases of sprue seen by him personally. Ashford (1932) in a review of 3,000 cases of sprue does not mention any signs or symptoms of this complication (quoted by Fairley, 1936).

PATHOLOGY AND BIOCHEMICAL FINDINGS

Since the introduction of liver therapy the uncomplicated case of pernicious anemia seldom comes to postmortem, but such was not the case previously and both the older pathologists and the older literature can give a detailed account of the findings. Details of the pathology of nutritional macrocytic anemia are not available owing to the difficulty of obtaining permission for postmortems in such cases. It is also regrettable that most of the little material that is available came from cases living in areas where malaria is endemic and which were all examples of so-called "hemolytic nutritional macrocytic anemia" (Fairley, 1938), these cases differ in important respects from uncomplicated ones, which for clarity will be referred to as nonhemolytic nutritional macrocytic anemia.

At postmortem the body in a case of pernicious anemia is usually that of a well-nourished, middle-aged or elderly man or woman, the skin and sclerotics and particularly all the fatty tissues are a bright lemon yellow color and there is an excess of fat in and around the organs. In contrast in nonhemolytic nutritional macrocytic anemia and in sprue the body is usually emaciated, fat being conspicuously absent from all the organs and the characteristic lemon yellow color of pernicious anemia is also missing, all the organs are extremely pale. A further feature of these two diseases is the great reduction in the size and weight of the organs, especially the heart and liver, which is in contrast to the findings in pernicious anemia where the organ weight is not reduced and may be increased. Fairley (1930) thinks this decrease in organ weight may be of diagnostic significance. At the postmortem of a case of nonhemolytic nutritional macrocytic anemia, a male of about 23 years of age, the body weight was found to be under 6 stone, though he was of average height for an Indian and the heart weight was only 140 grams (Wills, unpublished). Mackie and Fairley (1929) report a heart weighing only 90 grams in a case of sprue that came to postmortem. In contrast are the findings in the hemolytic type of nutritional macrocytic anemia, in two incomplete postmortem examinations, on a pregnant woman and on a woman who had just been delivered respectively, (Fairley et al., 1938), the bodies were relatively well-nourished, subcutaneous fat was plentiful and of the same bright lemon yellow

color as is seen in pernicious anemia. The organs, particularly the liver and spleen were enlarged and the heart, examined only in one case, showed some fatty degeneration.

The hemopoietic organs and the blood picture are of particular interest in the three diseases. The classic picture of a panhemopoietic dystrophy characterized by a megaloblastic erythropoiesis, a similar disturbance in the myeloid series with pathologic macro-myeloid cells and a reduction in number and abnormality in type of the thrombocytes, is present in all three conditions and the general opinion is that the changes in the cells in marrow and blood are identical in the three diseases. But both in sprue (Mackie and Fairley, 1929) and in nutritional macrocytic anemia (Balfour, 1927, Mitra, 1931, Wills, unpublished) examination of the tibia may show an aplastic marrow with a curious gelatinous appearance in the shaft, though in other cases the red marrow may extend from end to end of the bone. In nutritional macrocytic anemia in monkeys the tibial bone marrow may show similar red and gelatinous changes with a megaloblastic hyperplasia (Wills and Stewart, 1935). The detailed picture in the bone marrow revealed by sternal puncture preparations varies from case to case with the severity of the anemia and with complicating factors, but the essential pathology is the same and the changes resulting from adequate treatment with liver or folic acid are also the same. But there is a remarkable difference in the blood condition which has not been adequately stressed. In true pernicious anemia in relapse there is some factor constantly present which causes an increase in the serum bilirubin which gives rise to the characteristic coloring of the skin, sclerotics and of the body fat and also to an increased output of urobilin or urobilinogen in the urine and feces. Fairley (1941) has also shown the presence of methemalbumen in the plasma, which is taken as evidence of intravascular hemolysis. In uncomplicated cases of tropical nutritional macrocytic anemia in relatively nonmalarious areas and in uncomplicated cases of sprue the findings are in marked contrast to those in pernicious anemia in relapse and in the hemolytic type of nutritional macrocytic anemia as shown in table 1.

Earlier figures, lost during the blitz, from a larger series of cases of nonhemolytic nutritional macrocytic anemia gave similar findings, the mean figure for 50 cases being 0.33 mg per 100 ml. Only 1 in 36 cases had urobilin or urobilinogen in excess in the urine. In the hemolytic type of nutritional macrocytic anemia seen in Macedonia the serum bilirubin in the cases reported by Fairley and colleagues (1938) was markedly raised, the mean figure being approximately double that of the author's series of untreated cases of pernicious anemia (see table 1). In an earlier series of 48 cases of sprue seen in Bombay by Fairley only 3 had bilirubin values above 0.6 mg per 100 ml. In a series of cases of "sprue" seen in Puerto Rico (Castle et al., 1932) the icterus index was determined in 89 individuals, in 24 it was above 6 units, which was almost as great an incidence of a raised value as in the same authors' series of cases of pernicious anemia. It is difficult to assess these figures as Puerto Rico is a malarious area. The difference in the figures for serum bilirubin and urinary urobilin or urobilinogen in the different clinical entities suggests that in untreated pernicious anemia and in the hemolytic type of nutritional macrocytic anemia there is a hemolytic factor which is absent in uncom-

plicated nutritional macrocytic anemia and sprue. The postmortem findings, though these are scanty in nutritional macrocytic anemia, are of interest in this connection.

The characteristic deposits of iron found in the liver, spleen, bone marrow and kidneys in pernicious anemia are not considered by most recent workers to be an index of increased hemolysis but rather of an inability of the blood forming organs to deal with the iron liberated by normal blood destruction (Minor and Strauss, 1943). But the iron in the kidneys is deposited within the cells of the excreting tubules, particularly in the proximal tubules, the glomeruli containing no iron pigment. Muir and Young (1941) have shown that large amounts of hemosiderin may be deposited in the cells of the tubules as a result of a hemolysis insufficient in degree to cause hemoglobinuria, and they suggest that these deposits in the kidney in pernicious anemia are due to such a hemolysis. Evidence in support of this view is the presence of methemalbumen in the plasma (Fairley, 1941). There are insufficient adequate postmortem studies to compare the hemosiderin deposits

TABLE 1 — *Serum Bilirubin Values*

in complicated nutritional macrocytic anemia and sprue with those in pernicious anemia. The size of the liver and spleen are of some interest in this connection. In pernicious anemia both organs are commonly moderately enlarged and show the characteristic deposits of hemosiderin and may show areas of extra medullary blood formation, fatty changes are very marked in the liver. In nutritional macrocytic anemia the size of the liver and spleen appears to vary with the geographic locality and the malarial infection rate. In Bombay, particularly in the male cases, these organs were rarely palpable and in the 2 postmortems the size of the organs was reduced, in one case the liver weighed only 630 grams and the spleen 120 grams, both organs gave a positive Prussian blue reaction. In some of the female patients both organs were just palpable. In Calcutta, British Guiana and Macedonia, all highly malarious areas, the findings differ markedly. Napier (1941) using pregnant cases, reports "a very marked association" between splenomegaly and severe macrocytic anemia, and in 6 out of 44 cases the spleen was below the navel.

In most of the cases with enlarged spleens the liver was also enlarged and there was a definite correlation between a raised Van den Bergh and enlargement of these organs. There was also a strong suggestion that there is some association between a positive Wassermann reaction and a macrocytic anemia. Giglioli (1934) found the spleen enlarged, generally to below the umbilicus, in 94 per cent of his cases of macrocytic anemia and associated in the majority of cases with a raised serum urobilin. There was a marked positive correlation between the spleen and parasite rate and the incidence of the anemia, which suggests, he thinks, that chronic malarial infection is 'a factor of very considerable importance' in the etiology of nutritional macrocytic anemia. In Macedonia the vast majority of the cases had grossly enlarged spleens.

In 2 cases of nutritional macrocytic anemia dying after parturition, postmortem examination (Balfour, 1927) showed very slightly enlarged spleens which, with the livers, gave a positive Prussian blue reaction. In the 2 cases of hemolytic nutritional macrocytic anemia in pregnant women examined postmortem by Fairley and colleagues the liver was very enlarged in 1 case with nutmeg changes from heart failure, and moderately enlarged in the other, both livers showed marked hypertrophy of the reticulo-endothelial cells with swollen Kupffer cells, phagocytosis and proliferation in the sinusoidal system. Malarial pigment was present in some of the Kupffer cells and hemosiderin in the liver cells, particularly in the outer zone of the lobules. The spleen was enlarged and hard in both cases (25 and 22.7 ounces respectively) and showed a hyperactive reticulo-endothelial system with some malarial pigment in the cells and a reduction in the lymphoid tissue, the hemosiderin was less than in the liver. The kidneys gave a negative Prussian blue reaction. Mitra (1931) found similar changes in material from cases in Calcutta which were probably hemolytic, but in his cases there was a fatty degeneration of the central part of the lobule with extravasation of blood.

The other systems of particular interest are the alimentary and nervous systems. In all three conditions the tongue may show characteristic changes but these may be absent and are not specific, as very similar changes occur in microcytic anemia and in pellagra. Abnormalities of the stomach and intestines may be present in all three diseases and are of fundamental importance in pernicious anemia. Many workers, particularly Castle et al., (1935) have compared the gut changes in pernicious anemia and 'sprue' with those seen in pellagra and have stressed the atrophic tongue changes and the diarrhea, and the similar effect of treatment on these states in all three conditions. The dramatic effect of folic acid on the intestinal symptoms in pernicious anemia, nutritional macrocytic anemia and sprue also suggests that the lesions of the alimentary tract are similar in all three conditions. But though this may be true of the final state of the fully developed disease, the basic pathology would appear to be different in the three entities. The classic work of Magnus (1938) and Meulengracht (1939) has shown that the fundamental change in pernicious anemia is an atrophy, possibly genetic, of the mucosa of the fundus of the stomach and it is this lesion which appears to lead, by the production of an abnormal gastric juice, to a failure in the supplies of the liver factor or factors necessary for proper hemopoiesis and for the good health of the central nervous

system Jacobson (1939) would correlate the presence of similar hemopoietic properties to those of liver in dessicated stomach and small intestine to the presence of argentaffin cells, which are markedly reduced in pernicious anemia, both in the atrophic gastric mucosa and in the intestine. The characteristic changes in the gastric mucosa seen in all true cases of pernicious anemia are absent from the gastric mucosa of monkeys suffering from nutritional macrocytic anemia (Magnus—from a study of our material—unpublished) so presumably they are also absent from the stomach in human nutritional macrocytic anemia. The presence of free hydrochloric acid in normal amounts would also suggest that the mucosa is undamaged. Suitable material for the study of possible changes in the gut in nutritional macrocytic anemia is not available but from analogy with animal material there is probably a thinning of the gut wall due to the general emaciation and little else in the small intestine. Nonspecific ulceration of the large intestine was seen in one tropical case that came to postmortem (Wills, unpublished). The importance, in the examination of the intestines, of fixation immediately after death is well illustrated in the postmortem reports on cases of sprue. In 1929 Mackie and Fairley reported changes in the small intestine which they considered "begin as an inflammation but pass on to degenerative changes" (Fairley, 1930). More recent work (Mackie and Fairley, 1934) on material fixed immediately after death has failed to reveal any pathologic change except slight congestion of the margins of the valvulae connivents and these authorities consider that the changes in the gut which result in such profound metabolic disturbances are functional and not pathologic. Hanes (1942) confirmed this absence of pathologic change, except extreme emaciation, in 4 fatal cases of sprue. Koppisch (Suarez et al., 1947) reported the postmortem findings in 16 cases of "sprue" in Puerto Rico. He found evidence, but it may have been a postmortem artifact, of chronic gastritis in all but 3 cases and moderate atrophy of the gastric mucosa in half the cases. Gastroscopic examination confirmed the presence of atrophy of the gastric mucosa (Rodriguez-Olleros, 1938, Hernandez-Morales, 1944), but Rodriguez-Olleros considers that this atrophy results from the disease and does not precede it, as the atrophy was only found in fully developed cases. Hernandez-Morales found that after treatment the mucosa in many cases became normal again. Koppisch also reported a definite shortening and blunting of the villi of the small intestines, with an associated increase in the number of plasma cells in the tunica propria in half the cases examined. As in nutritional macrocytic anemia in monkeys and man, inflammation and nonspecific ulceration were found in the colon of the majority of the cases.

The nervous lesions of subacute combined degeneration of the cord, so characteristic of pernicious anemia, are rarely, if ever, seen in true tropical sprue or nutritional macrocytic anemia. Peripheral neuritis may occur in all three conditions but is an inconstant finding due to an associated dietary deficiency in the vitamin B complex in the nutritional cases and probably to conditioned deficiency in the case of sprue.

Chemical examination of the gastric juice in the three conditions shows a complete and persistent histamine resistant achlorhydria associated with achylia and absence of the intrinsic factor in true pernicious anemia, in nutritional macrocytic

anemia and sprue the gastric acid varies from hyperchlorhydria to hypochlorhydria and achlorhydria, the last being more frequent in cases of sprue than in cases of nutritional macrocytic anemia. The amount of intrinsic factor present in the gastric juice of such cases is also variable, being absent in some cases of sprue (Castle et al, 1935) and in certain cases of nutritional macrocytic anemia associated with pellagra (Moore et al, 1944). It has not been possible to test the gastric juice of cases of uncomplicated tropical nutritional macrocytic anemia, as no cases of true pernicious anemia were available in Bombay for test purposes.

Various biochemical tests are now used for the diagnosis of sprue, the most important being the fat content of the stool, the fat absorption test and blood lipid curves and the oral glucose tolerance test. It is doubtful whether any of these can be considered to give specific diagnostic results as similar findings to those usually obtained in sprue cases are also found in other conditions, such as multiple vitamin B complex deficiencies, but in conjunction with a typical history and clinical picture these tests can confirm the diagnosis. In sprue the stools are typically bulky, pale and fermenting, the color being commonly pale but dark colored stools being not uncommon (Black, 1945). The stools contain an excess of fat, the greater part of which is split. Fat balance experiments show a decreased absorption and though after treatment the diarrhea may be controlled and the percentage of fat in the stools decreased, fat absorption is still defective and it may be some considerable time before it improves (Black et al, 1946, Davidson et al, 1947). In nutritional macrocytic anemia the stools frequently appear normal (Wills, unpublished, Walters et al, 1947). Fairley and colleagues (1938) give figures showing a low fat content with normal ratio of split to unsplit fat. Such values would be expected in most of the cases as poverty limits the fat intake. A dietetic survey in Bombay among the families of patients with nutritional macrocytic anemia showed that the average daily consumption per adult was 45 Gm, of which 20 Gm was animal fat (Wills and Talpade, 1930). Cook (1944) and Chandhuri (1944) have described a spruelike condition in the civil population in India associated with macrocytic anemia and diarrhea but the diarrhea was watery and not fatty in both series. Walters (1947) and Girdwood (Davidson et al, 1947) however, describe a steatorrhea in a deficiency syndrome resembling sprue in Indian soldiers. In certain of these cases the diarrhea improved with nicotinic acid and in many sulphaguanidine controlled it, suggesting an underlying infective condition (Marriott, 1945, Chandhuri and Chandhuri, 1944).

The typical flat oral glucose curves that occur in sprue are not found in the uncomplicated case of nutritional macrocytic anemia (Fairley et al, 1938) but in those cases associated with a spruelike syndrome flat curves are found in a few instances (Chandhuri and Chandhuri, 1944).

TREATMENT

Since the epoch making discovery of Minot and Murphy of the therapeutic activity of liver in pernicious anemia, treatment of this and other allied macrocytic anemias has involved the use of different liver extracts, with stomach preparations, and in the nutritional cases with various so-called sources of Castle's extrinsic

factor But until recently, when the discovery of the hemopoietic activity of folic acid and its conjugated forms at last gave workers a chemically pure active substance, no pure substance with similar activity was available, the various factors postulated in Castle's theory of the formation of the liver principle and the principle itself having remained elusive This fact makes the interpretation of the activity or inactivity of different so-called purified preparations difficult, as varying doses mean varying amounts of substances other than the liver principle which, when massive doses are given, may be present in large enough amounts to be active This may explain certain of the contradictory results reported in the treatment of nutritional macrocytic anemia with some of the more highly purified extracts

It is not proposed to go into the vast literature on the therapeutic use of liver and stomach extracts and of folic acid but only to deal with those aspects of this work which have a bearing on the etiology of the three conditions under consideration In the early days of crude extracts, pernicious anemia, nutritional macrocytic anemia and the macrocytic anemia of sprue all responded well to liver preparations It was originally thought that nutritional macrocytic anemia was due to a lack of Castle's 'extrinsic' factor but doubt was thrown on this explanation when it was found that relatively purified extracts, known to be potent in cases of pernicious anemia in relapse, were completely inactive in the same or larger doses in the nutritional macrocytic anemia of monkeys, though campolon, a very crude liver extract was active curatively in relatively small doses (Wills et al, 1937) This work was confirmed by the same authors (1938) in a series of cases of nutritional macrocytic anemia in Bombay, by Napier (1939) in Calcutta, though he found that large doses of the same "purified" extract as that used by Wills and co-workers was active curatively in a few cases, and by Giglioli in Central America (personal communication) Various workers in different parts of the world have shown that "purified" extracts may be active in certain types of nutritional macrocytic anemia, as for example that occurring as a complication of pellagra (Moore et al, 1944) and in enormous doses in the hemolytic type in women, particularly in pregnant women in Macedonia but not in men in the same area (Fairley et al, 1938, Foy, 1939) Cases of nutritional macrocytic anemia also respond to marmite (autolysed yeast) and other so-called good sources of the extrinsic factor when given by mouth Recently Castle and co-workers (Watson and Castle, 1946) have shown that more than one type of nutritional macrocytic anemia occurs one that responds as pernicious anemia does to the highly purified liver extracts given parenterally in normal doses, another that responds to an unknown factor, "Wills factor" as Castle calls it, present in crude liver extracts and yeast, given either orally or parenterally, but not to purified liver extracts given parenterally, and finally one that responds to purified liver extracts given parenterally when the dose is increased tenfold Such an enormous dose might contain sufficient "Wills factor" to produce a remission

In sprue the macrocytic anemia has been shown to respond to marmite by mouth, to crude liver extracts by mouth and parenterally and also in many cases to purified liver extracts parenterally A high protein diet increases the hemopoietic effect

Finally folic acid has been shown to produce remarkable hemopoietic responses

in all three diseases. In pernicious anemia folic acid, either parenterally or orally, induces in the vast majority of cases a maximal reticulocyte response followed by an immediate rise in the red and white cell counts. The dose necessary to produce this effect is 5 to 10 mg daily or a single dose of 100 mg. Jacobson (1947) by incubating folic acid with the enzyme xanthopterase, has thereby enormously enhanced the hemopoietic activity of the folic acid, and he suggests that by this means folic acid has either been converted into Castle liver principle itself or into another compound with great hemopoietic activity. It is of interest in this connection to note that both the cases of pernicious anemia treated with the incubated material showed a steady rise in the red cell count and hemoglobin percentage to normal levels, the count reaching the 50 million level and the hemoglobin a corresponding one. This is in contrast to most workers' experience with folic acid, they find that often, after an excellent initial response, it is impossible, even with increasing doses, to get or maintain the blood at really optimal levels (Wilkinson, 1947, Davidson and Girdwood, 1947, Goldsmith, 1947, Meyer, 1947). Folic acid produces in all three of the anemias under consideration an immediate sense of well-being, of the same order as that produced by an active liver extract. But again in the treatment of nutritional macrocytic anemia the blood fails to reach normal values and macrocytosis persists, this is particularly so in cases of nutritional macrocytic anemia with diarrhea and also in cases of sprue, though the general clinical improvement is remarkable (Davidson et al, 1947, Morrison and Johnston, 1947, Suarez et al, 1947). It also has a miraculous effect in controlling the diarrhea of sprue and nutritional macrocytic anemia, though analyses have shown that in spite of the steatorrhea being decreased there is no immediate alteration in fat absorption (Suarez, Spies and Suarez, 1947, Davidson et al, 1947, personal cases).

In contrast to the general dramatic improvement is the complete ineffectiveness of folic acid treatment in arresting or preventing the development of symptoms of subacute combined degeneration (Spies and Stone, 1947, Wilkinson, 1947). The significance of these findings will be reviewed in the discussion on etiology of these three diseases.

In brief it can be said that pernicious anemia, including the symptoms of subacute combined degeneration can be successfully treated and health maintained with crude or purified liver extracts given parenterally or orally and proteolysed liver extract by mouth, by different preparations of hog's stomach by mouth and by digests of beef muscle or autolysed yeast with normal human gastric juice. Folic acid and its conjugated forms (Spies et al, 1947) produces a remission, which is often suboptimal, of the hematologic symptoms, an immediate sense of well-being but no effect on the nervous symptoms, the hematologic effect is said to be enhanced by incubation with xanthopterase.

Nutritional macrocytic anemia, both the nonhemolytic and hemolytic types seen in endemic form in many tropical countries, responds to crude liver extracts parenterally or by mouth and to autolysed yeast extracts (Wills, 1938, Napier, 1939). Relapses do not take place after cessation of treatment if the diet is improved. Folic acid has, in the few cases reported, the same action as in pernicious

anemia (das Gupta and Chatterjee, 1946) * The hemolytic type seen in Macedonia is very resistant to treatment but some cases respond to enormous doses of both crude and purified liver extracts and to very large oral doses of marmite (Fairley et al, 1938, Foy and Kondi, 1939)

The treatment of sprue has been studied by Fairley (1936) in cases largely from India and the Far East, by a group of workers in Cuba and Puerto Rico (Spies et al, 1946-47) and by the service authorities in India and the Far East where the disease was of relatively rapid onset (Leishman, 1945, Macgraith et al, 1945, Keele and Bound, 1946) All agree that for optimal improvement a high protein diet with liver extract or folic acid are required In the critically ill, blood transfusion may be necessary and in the service cases sulphaguanidine often controlled the diarrhea The high protein diet leads to an improved nutrition, as the absorption of protein does not appear to be affected

PATHOGENESIS AND DISCUSSION

Our present knowledge of the three clinical entities described supports, in the author's opinion, the view that they are three distinct separate diseases, with essentially different natural histories and pathological pictures It is now proposed to discuss the evidence for this belief in the light of the facts set out in the previous paragraphs Authorities will not be quoted when they have already been given It is proposed to limit this discussion to the classic conditions as generally understood Pernicious anemia is a well recognized disease in which a persistent achylia gastrica is a diagnostic feature The title nutritional macrocytic anemia is limited to the disease as seen in endemic areas but will include sporadic cases occurring in other parts of the world, but to simplify the discussion the sporadic cases of "pernicious" or "macrocytic" anemia of pregnancy will not be considered, as it is felt that this group probably includes several different entities Tropical sprue is less well defined and recent experience in the services has led to the inclusion under this title of certain relatively acute conditions closely resembling sprue, but not yet sufficiently worked out to be definitely included under the title of "tropical sprue," which for the purposes of this discussion will be limited to the classic disease as described by workers from Hillary in 1759 to Fairley in 1938 The service cases and "sprue" as seen in Puerto Rico will be discussed in relation to the classic picture

A consideration of the geographic, ethnic, and social distribution of these three diseases leads to the conclusion that they are three separate entities Pernicious anemia is a familial disease of persons of European descent, with certain very definite genetic characteristics, the distribution of the disease corresponding to that of the racial groups affected, chiefly fair and Nordic peoples Individuals of all classes are affected In marked contrast is the distribution of nutritional macrocytic anemia This disease occurs mainly in tropical and subtropical lands, but the

* Since the writing of this paper, Kemp (Lancet 2 351, 1947) has reported 3 cases of nutritional macrocytic anemia who showed remarkable improvement with folic acid but were not studied long enough to show whether the blood level would have reached completely normal values and whether the macrocytosis, still present with red cell counts at the 4 million level, would have disappeared

distribution is associated with poverty, a low calory, largely or entirely vegetarian diet, with pregnancy and lactation and also with certain diseases such as syphilis and particularly chronic malaria, which result in a hypertrophied reticulo-endothelial system. It also occurred in vegetarian Indian troops under the stress of service conditions and in Indian prisoners of war. An anemia considered the animal counterpart of the human disease can be produced in monkeys by feeding with a diet based on one in common use among sufferers from this disease. Pregnancy and lactation are known to increase the maternal requirements and these conditions will convert a latent deficiency into an overt one. The relation of chronic malaria to this anemia will be discussed later. These findings strongly suggest a direct nutritional origin, in other words that this anemia is an unconditioned deficiency state. The fact that this anemic syndrome is often associated with other symptoms including diarrhea, often watery but sometimes fatty, referable to a vitamin B₂ deficiency supports the view that the anemia is a deficiency state. The geographic, ethnic, and social distribution of tropical sprue presents a much more difficult problem. Classic sprue has generally a gradual onset and is associated with residence in a warm climate but affects Europeans rather than pure Indians or Negroes. The nature of the illness, which is generally afebrile throughout, throws little light on the etiology but the result of treatment suggests a deficiency state. Though this certainly exists in the fully developed syndrome there is little evidence for a nutritional origin for the altered intestinal absorption which conditions the deficiency. A more detailed examination of the distribution of the condition, the heavy incidence in certain areas in the large endemic zones and even in certain houses, combined with the fact that very many sprue patients come from the ranks of the well-fed, suggests a possible infective agent as the primary cause but this is purely conjectural. A consideration of the outbreaks of acute sprue in the service is of interest in this connection, though further study is necessary before these can be definitely considered the same clinical entity as classic 'tropical' sprue. Sprue in service personnel showed the same concentration in certain districts and sometimes in certain camps, explosive outbreaks which assumed epidemic proportions in certain areas also occurred. Leishman (1945) reports from Chittagong that nine separate units were affected, some with a 50 per cent attack rate and one R A F unit had 10 per cent of its personnel down with diarrhea three weeks after its arrival in India, which diarrhea rapidly turned to the sprue syndrome. These findings are very strongly suggestive of an infective origin for this type of sprue.

A study of the pathologic and biochemical findings in these diseases supports this idea of their essential individuality. The pertinent findings in pernicious anemia are the atrophic changes in the fundus and cardia of the stomach, with its associated achylia gastrica, the increased plasma bilirubin, the presence of methemalbumen in the plasma, the distribution of iron in the tissues and other evidence of a hemolytic factor in the anemia and the changes in the central nervous system characteristic of subacute combined degeneration of the cord. The atrophy of the gastric mucosa would appear to be the basic defect, it involves all the coats of the stomach wall and results in a complete histamine resistant achlorhydria and an associated achylia. There is no evidence of preceding inflammatory processes and

Magnus (1938) thinks the evidence points to the change being the final stage of an atrophic process, the cause of which is unknown but might be ' the end result of some endocrine or nutritional deficiency or might even be congenital in origin ' ' The evidence for the genetic factor is the familial and racial incidence and the lack of any indications of an infective, nutritional or endocrine origin. Idiopathic hypochromic anemia, an iron deficiency anemia associated with achylia gastrica also occurs in families subject to pernicious anemia (Wintrobe and Beebe, 1933). In sprue an atrophy of the gastric mucosa has been reported by the Puerto Rico workers but the evidence points to it being secondary to the disease, as it occurs only in the fully developed syndrome. Mackie and Fairley, from a study of specially fixed material, report a normal mucosa. In the nutritional macrocytic anemia of monkeys there is no significant change in the gastric mucosa and presumably the mucosa is normal in the corresponding human conditions. Test meal findings confirm the essential normality of the gastric mucosa in most cases of sprue and nutritional macrocytic anemia. The defect in the gastric mucosa seen in pernicious anemia according to Castle's well known theory produces a lack of his intrinsic factor, a substance with enzymic properties, and it is this deficiency that leads to the failure of the formation of the liver principle. Castle's work has shown the mode of action of this intrinsic factor, but neither it nor the extrinsic factor have been isolated, any more than the liver principle itself.

This defect in the gastric secretion, with its interference with the formation of the liver principle and possibly with another principle essential for the proper functioning of the nervous system, appears to be the basic lesion in pernicious anemia, but unless we accept the view that a certain variable time is necessary for the postulated genetic factor to bring about this gastric atrophy it is necessary to look further for a factor producing this atrophy, from the evidence it seems that there is little to suggest an inflammatory one. This same time factor in the development of the symptoms of pernicious anemia appears to operate in those cases which develop the disease after total gastrectomy, a period as long as ten to fifteen years occurring between the time of operation and the time of development of symptoms (Meyer et al, 1941). This time lag is also unexplained. In this connection Rhoads's (1933) experiments on the production of a syndrome resembling pernicious anemia in hogs by feeding modified black tongue diets are of interest. The deficiency not only produced tongue changes, a macrocytic anemia and nerve lesions, but a histamine resistant achlorhydria, this syndrome, though it resembled that of pernicious anemia, differs from it in that the gastric changes are reversible and the condition could be cured, whereas in true pernicious anemia replacement therapy is always necessary, the primary lesion being irreversible.

Another experiment of interest in this connection is that of Petri (1944) and co-workers, these authors have shown in experiments on dogs and swine that total gastrectomy produces signs of pellagra, due apparently to interference with absorption of nicotinic acid. Furthermore the livers from such pigs were ineffective in the treatment of pernicious anemia. However, nicotinic acid by the parenteral route compensated in these animals for the absence of gastric secretion, the livers from gastrectomized pigs receiving parenteral nicotinic acid being fully effective.

in pernicious anemia in relapse. This experiment indicates one of the factors that may influence the formation of the liver principle and may explain the pathogenesis of those macrocytic anemias which respond to nicotinic acid (Cook, 1944).

The hemolytic process seen in pernicious anemia is of great importance both in a consideration of the essential pathology of the disease and in considering its relationship to nutritional macrocytic anemia and sprue. There is little to explain the increased serum bilirubin and other evidence of increased red cell destruction except that it ceases under appropriate treatment with liver, hog's stomach or folic acid and might, therefore, be thought to be due to the nature of the macrocytes. There is, however, no increased fragility of the red cells and no hemolysis has been demonstrated in the blood stream but there is evidence of active phagocytosis of the red cells in the reticulo-endothelial cells of the bone marrow, liver and spleen, which might account for some of the increased bilirubin in the circulation. But the presence of methemalbuminemia and a positive Schumm test would suggest some additional intravascular hemolysis (Fairley, 1941). With certain exceptions already mentioned, there is no evidence of hemolysis in either nutritional macrocytic anemia or sprue and as the megaloblastic reaction is generally considered identical in all these anemias, it is unlikely that the hemolysis in pernicious anemia is due entirely to the nature of the cell. It would appear more likely that it is due to an association of an overactive reticulo-endothelial system with abnormal cells, though the cause of this hypothetical increased activity is unknown. The evidence of increased hemolysis seen in cases of nutritional macrocytic anemia occurring in areas of endemic malaria supports this view.

Tropical sprue is a dramatic disease in which spectacular pathologic changes in the tissues might be expected but postmortem examinations have failed to reveal any anatomic changes except those in the bone marrow and those of extreme inanition, the loss of fat and shrunken organs. There are no lesions of the nervous system as in pernicious anemia. Histologic examination of material from the gastrointestinal tract fixed immediately after death has shown essentially normal structures. The changes in the gut are functional and not anatomic. In a brilliant review of recent work Stannus (1942) has marshalled the evidence for a failure of phosphorylation of fatty acids, glycerol and glucose being the basic lesion, the point of functional breakdown. There is much evidence in support of this view. Maeraith and colleagues (1945) have shown in cases of spruelike conditions that in the active phase the absorption of glucose is grossly impaired though that of fructose is not, suggesting that there is an impairment of phosphorylation of glucose, although the diffusion of sugars across the membrane is unaffected. Leishman (1945) suggests that the vitamins riboflavin and nicotinic acid are concerned in this process of phosphorylation, in their phosphorylated forms as co-enzyme I and yellow oxidase they take part in cellular metabolism, acting as H acceptors or rejectors and Leishman thinks it is possible that they may catalyse the process of phosphorylation. It is possible that some other member of the vitamin B₂ complex takes part in this process. But if the failure in phosphorylation is due to deficiency of any B vitamin how does this deficiency arise in well-fed people and why did it not occur among prisoners of war in Japanese hands, who suffered so badly from

deficiencies of these vitamins Leishman points out in this connection that the B vitamins are synthesized in very appreciable amounts in the gut, and that a change of diet or dysentery might alter the balance of the intestinal flora and hence of vitamin synthesis Work along these lines might be illuminating

Pathologic and biochemical observations throw little light on the essential pathology in nutritional macrocytic anemia As in pernicious anemia and sprue the hemopoietic organs show the changes characteristic of a macrocytic anemia but both in nutritional macrocytic anemia and in sprue the bone marrow from the tibia (the bone examined) may show gelatinous changes as well as the extension of the red marrow characteristic of pernicious anemia Beyond these changes and those due to inanition there are no obvious pathologic lesions Magnus has shown the presence of a normal gastric mucosa in material from monkeys suffering from nutritional macrocytic anemia In man the gastric acidity and the blood sugar levels after oral glucose fall within normal limits There is no evidence of increased hemolysis, except in areas with a high incidence of malaria Fairley and Foy have given detailed accounts of this type in which the increased serum bilirubin values, a positive Schumm test, the increased urobilin output, the yellow color of skin and body fat are all indications of an increased hemolysis The spleen is enormously increased in size, frequently the liver also and postmortem material has shown a hyperactive reticulo-endothelial system Fairley sums up the picture thus "A reticulo-endothelial system irritated, activated and hypertrophied as a result of repeated malarial infections, phagocytoses these non-parasitized, abnormal corpuscles in considerable numbers, producing a haemolytic anaemia " The corpuscles are abnormal macrocytes, the result apparently of a marrow rendered megaloblastic by a deficiency of the same nature as that operation in uncomplicated nutritional macrocytic anemia

It has been suggested in the preceding paragraphs that these three diseases all exhibiting an apparently identical panhemopoietic dystrophy are distinct clinical entities It can be postulated that this dyshemopoietic anemia probably results from the breakdown of some intracellular enzyme system in which the liver principle plays an important part The relation of folic acid to this system still awaits solution but the fact that it has such remarkable, if limited, hemopoietic activity in all three conditions, as well as a dramatic effect on the well-being of the patient and on diarrhea if present, shows that it plays an all important role in rectifying the faulty cellular metabolism The liver principle is active curatively in pernicious anemia but does not seem to be the missing factor in nutritional macrocytic anemia as it has been shown to be inactive in this anemia in man and monkeys in doses equivalent to or greater than those giving maximal responses in cases of pernicious anemia with similar initial blood levels That this factor, ' Wills' factor ' as Castle calls it, is not Castle's extrinsic factor follows from the fact that the ' liver principle ' in purified preparations is inactive in nutritional macrocytic anemia Recent work on the relationship of folic acid to vitamin M deficiency in monkeys (Day, et al , 1945 and 1946, Wilson, et al , 1946) suggests that possibly folic acid is the missing factor It is possible that ' Wills' factor ' is an activator or co-enzyme in an enzyme system in which the liver principle plays the important part

Other factors may also be concerned and a deficiency in any one of these might produce a similar failure in the function of the liver principle

Finally it is interesting to consider these three entities from the point of view of preventive medicine. If a genetic defect is the ultimate cause of pernicious anemia then only selective breeding, at present a Utopian and risky measure, can eradicate it. If, as seems highly probable, nutritional macrocytic anemia is a deficiency disease due to a lack in the diet of some factor associated with good biologic protein, then improved economic conditions with the improved diet that always goes with them should eradicate the disease, except in those cases where religion limits the diet when only a new revelation can assist. But the problem of sprue awaits further work, as until we know the nature of the original cause of the intestinal breakdown it is impossible to take preventive measures.

SUMMARY

The following tentative conclusions as to the relationship of pernicious anemia, nutritional macrocytic anemia and tropical sprue to one another and their pathogenesis are drawn from a study of the literature and from unpublished work

- 1 That these three clinical conditions are three distinct entities possessing a common characteristic in the presence of a panhemopoietic dystrophy characterized by a megaloblastic erythropoiesis and corresponding changes in the myeloid cells and platelets

- 2 That this panhemopoietic dystrophy possibly results from the breakdown of an intracellular enzyme system but that the deficiencies causing the breakdown differ, in pernicious anemia the liver principle is apparently at fault, in endemic nutritional macrocytic anemia another unidentified factor is missing, in sprue either or both may be at fault

- 3 Folic acid is active therapeutically in all three diseases, but in all it generally fails to restore completely normal blood levels

- 4 Pernicious anemia is probably due to a genetic defect which produces an atrophy of the gastric mucosa. As a consequence of this interference with gastric function there is a failure in the formation or absorption of the liver factor and possibly of another neurotrophic factor, which failure results in the development of a macrocytic megaloblastic anemia and the characteristic changes in the nervous system. Indefinite replacement therapy is necessary as the changes in the gastric mucosa are irreversible. The cause of the increased hemolysis is unknown

- 5 Endemic nutritional macrocytic anemia is an unconditioned food deficiency, the deficiency being in a factor other than the liver principle, possibly a co-enzyme present in or associated with good biologic protein and the vitamin B₂ complex. There are no characteristic pathologic changes except those of the hemopoietic organs which are not specific to the disease. A hemolytic type of the disease occurs in areas of high malarial incidence. After successful treatment the disease does not relapse if the diet is satisfactory. Pregnant women are particularly liable to develop the disease

- 6 Tropical sprue is due to a functional disorder of the intestine, possibly primarily a failure in phosphorylation of fatty acids, glycerol and glucose. Diarrhea

with characteristic stools and a macrocytic anemia are characteristic findings. The macrocytic anemia may be due to a failure in absorption of one or more essential hemopoietic factors or to a lack of Castle's intrinsic factor. The cause of the functional breakdown is unknown. Treatment is with a high protein diet and liver extracts. Relapses are common.

My thanks are due to my colleagues for carrying on my work while I wrote this paper.

THE RELATION OF THERAPY IN PERNICIOUS ANEMIA TO CHANGES
IN THE NERVOUS SYSTEM EARLY AND LATE RESULTS IN A
SERIES OF CASES OBSERVED FOR PERIODS OF NOT LESS
THAN TEN YEARS, AND EARLY RESULTS OF
TREATMENT WITH FOLIC ACID

By FRANK H BETHELL, M D , AND CYRUS C STURGIS, M D

THE FREQUENT occurrence of nervous system involvement in pernicious anemia, the characteristic localization of the lesions in the spinal cord, and the extension of the process before specific treatment became available, suggested to early observers a common cause of, or a cause and effect relationship between, the hematologic and neurologic manifestations of this disease. However, the absence of combined system degeneration or even peripheral neuropathy in many cases of pernicious anemia and the complete dissociation of the severity of the neurologic and hematologic features are not satisfactorily explained by these concepts. With the general acceptance of Castle's hypothesis of a conditioned metabolic deficiency as the basic mechanism responsible for the pernicious anemia syndrome the view was often expressed that the changes in the hematopoietic and nervous systems resulted from distinct deficiencies which, in turn, probably depended upon a primary defect in gastric function. Evidence for the existence of such separate deficiencies was difficult to obtain because of the lack of exact information pertaining to any of the metabolic factors involved.

When effective treatment of pernicious anemia was introduced by Minot and Murphy, the importance of evaluating the new therapy in the control of combined system degeneration was at once recognized. Over the past two decades many clinical reports bearing on this problem have been published, and an extensive review of the literature is not pertinent to the present communication. The diversity of results and conflict of opinions which characterized the earlier experiences with liver and stomach therapy have been largely explained as due to differences in the conditions of observation and in the amount and potency of the medications employed and the modes of their administration. It is now the consensus of most observers that with individualized optimal therapy the progress of disease of the spinal cord can be arrested in every patient with pernicious anemia unless serious complications are present, that the probability of improvement of the neurologic status and the extent of the benefit which may be expected are inversely related to the duration of the process at the time of institution of therapy, that the period during which improvement may be anticipated is largely limited to the first few months after commencement of intensive treatment.

The regular administration by the intramuscular route of potent liver extract in doses adjusted to the needs of the individual, controlled by periodic clinical and hematologic evaluation, is almost a guarantee against further nervous system

From the Thomas Henry Simpson Memorial Institute for Medical Research, and the Department of Internal Medicine, University of Michigan, Ann Arbor, Michigan

damage. Such an ideal therapeutic regimen, however, is not employed in the actual management of many cases of pernicious anemia. Particularly is this true of those patients who live at a distance from their physicians, those who change physicians, and those who are seriously influenced by economic considerations. It therefore becomes important to evaluate the results of therapy over a long period of time in a series of cases presenting varied manifestations of the disease and differing with respect to type and amount of therapy received. It is well recognized that patients with previously active neuropathies who discontinue treatment, or those whose therapy becomes so inadequate as to permit development of pronounced anemia, almost invariably suffer reactivation of their neurologic process. It is also true, although less commonly observed, that patients without previous evidence of nervous system involvement may acquire neurologic manifestations after omission or gross inadequacy of anti-pernicious anemia therapy. It may not be so easy, however, to demonstrate a close relationship in all cases between the progress of disease of the nervous system and continued or recurrent suboptimal therapy, as evidenced by relatively slight disturbances of erythrocyte values.

The 70 patients comprising the first series to be reported have all been under observation at the Simpson Memorial Institute for ten years or longer. When seen initially they were in hematologic relapse and had received no effective antianemia therapy for at least several months prior to their first examination. Fifty-eight of the patients were previously undiagnosed and untreated. The diagnosis was established by the clinical and hematologic features characteristic of pernicious anemia, by the absence of other demonstrable conditions associated with macrocytic anemia, by the invariable presence of histamine refractory achlorhydria, and by the therapeutic response in every instance to the administration of potent anti-pernicious anemia medication. The neurologic status was evaluated and the cases were classified on the basis of objective as well as subjective evidence of involvement of the peripheral nerves and posterior columns, or of the posterior and lateral columns, of the spinal cord. Although the distinction between evidence of peripheral neuropathy, posterior column disease only, and combined system degeneration is useful as an indication of the severity of the process and in the interpretation of therapeutic results, such a separation is by no means an exact one. The extent of the process in each patient was graded primarily on the basis of peripheral nerve and posterior column involvement as one plus to four plus, indicating, in order of increasing severity: 1 plus, diminution of vibratory sense and altered reflexes in the lower extremities with paresthesia, but without significant disability; 2 plus, loss of vibratory sense and impairment of sense of motion and position in the distal portions of the lower extremities, with mild ataxia; 3 plus, complete loss of vibratory sense in the lower extremities with moderate to severe ataxia; 4 plus, ataxic or spastic paraplegia with inability to stand unassisted, sometimes associated with sphincter disturbances. Evidences of improvement were likewise graded arbitrarily on a plus basis, according to which 4 plus signifies complete disappearance of all subjective and objective manifestations. Evaluation of degrees of improvement less than complete recovery is dependent upon the

extent of the pre-existing disease and so cannot be defined in terms applicable to all patients. In general, improvement of 3 plus indicates freedom from serious disability with persistence of some paresthesia, and with slight to moderate ataxia in patients who had had the more severe forms of neural involvement. Much of the improvement of these patients may be attributed to recovery from peripheral neuropathy, with education of new muscle groups and adaptation to altered proprioceptive pathways playing important parts. However, the greatly superior results of therapy in patients, often with extensive disease, whose neurologic manifestations were of short duration, suggests that in the early stages of spinal cord involvement, nerve recovery may occur.¹

The demonstration of unequivocal peripheral nerve changes in pernicious anemia²⁻⁵ explains the transient and fluctuating paresthesias which occur so frequently in this condition. Peripheral neuritis is probably always present during the active periods of combined system disease and it may occur in the absence of convincing evidence of spinal cord involvement. Patients whose sole neurologic complaint was variable paresthesia or tenderness in the extremities without demonstrable deep sensory disturbances were not considered to suffer from significant disease of the nervous system. Evidence of some degree of cerebral involvement was fairly common among the members of this series. Yet the multiplicity of factors which may have contributed to the production of mental changes in these patients, including anemia, malnutrition, and degenerative vascular disease, and the difficulties involved in comparative measurements on a group of advancing age, render the precise consideration of the mental status of doubtful significance in the evaluation of long-term therapeutic results.

Several types of therapy were employed in the initial management of these patients. Some of them were among the first cases of pernicious anemia to receive the benefits of the liver diet. A considerable number were seen before parenteral liver extracts became available. During the years there has been a tendency to substitute refined and concentrated preparations of liver extract for the cruder less potent parenteral extracts and for oral products. Nevertheless, a number of patients, largely for reasons of personal choice, have continued to take oral liver extract or desiccated stomach or the cruder parenteral liver extracts. It thus becomes possible to compare the effects of different kinds of therapy with respect both to initial responses and to the neurologic status after a long period of time. Moreover, the information afforded by this analysis may be used in the evaluation of results obtained with new types of antianemia medication. In this connection, a small series of patients treated with folic acid will be reported with particular reference to changes in the nervous system.

Of the 70 cases under observation for ten years or longer, there were 45 males and 25 females, giving percentages, respectively, of 64.3 and 35.7. This is a somewhat higher proportion of males than is found in our entire series of over 1,000 cases of pernicious anemia seen at the Simpson Memorial Institute, in which the percentage of males is approximately 55. The average age of the patients at the time of diagnosis of their disease was 53.8 years, and the age distribution for the two sexes was approximately the same. The youngest member of the series was 35 and the oldest

was 68. The lower age range of these patients as compared to that generally reported for pernicious anemia is, of course, explained by the fact that they were all followed for at least ten years after the diagnosis was made. The average length of the observation period in the case of the males was 13.4 years and for the females was 13.3 years.

Objective manifestations of disease of the nervous system were present in 67.1 per cent of the patients in this group. Serious disability on a neurogenic basis was present in 15.7 per cent, but only 4 patients, or 5.7 per cent, were unable to stand or walk without assistance. It should be pointed out that the low incidence of extremely severe central nervous system disease in this series may be accounted for by the fact that the commonest causes of death in pernicious anemia are the complications of spinal cord involvement.⁶ It is of interest, however, that, in some cases, such fatal complications may be prevented for an apparently indefinite period, even though serious disability has been present for a relatively long time before treatment is instituted. Although the incidence of neuropathy is approximately the

TABLE 1—*Extent of Neurologic Manifestations when First Seen*

	Number of cases		
	Males	Females	Total, both sexes
None (0)	14	9	23

Moderate (++)	17	8	25
Severe (+++)	3	4	7
Very severe (++++)	1	3	4
Total	45	25	70

same for the men and women of this series, the latter tended to have manifestations of more severe involvement when first seen (table 1). Nevertheless, the differences are not sufficiently great and the number of cases is too small to warrant separate consideration of the sexes with respect to the long term course of their disease.

The changes in the neurologic status may be correlated with the duration of symptoms referable to the nervous system before institution of therapy (table 2) and with the type of treatment given (table 3). Of special significance for the purposes of this study is the correlation of the long term results with the adequacy of therapy (table 4).

The better outlook for improvement in neural manifestations when these are of short duration was first pointed out by Ungley and Suzman in 1929,⁷ has been noted by numerous observers, and recently was re-emphasized by Rundles.⁸ The results of treatment of the patients in this series fully support this view, but in addition they indicate that even when symptoms have been present for longer than twelve months a considerable degree of improvement will occur in most cases (table 2).

Improvement in the neurologic status was essentially limited, in all cases, to the first year of treatment, and in fact most functional recovery took place during the

TABLE 2—*The Maximum Extent of Clinical Improvement in Neurologic Manifestations During Period of Adequate Therapy Related to the Duration of Neurologic Symptoms Before Treatment Was Begun*

P D signifies neurologic manifestations progressed in severity or developed during observation

o signifies neurologic status remained essentially unchanged

— signifies absence of neuropathy, hence, no room for improvement in the disease process

first six months. The results are about equal for the different types of therapy employed, including desiccated stomach, whole cooked liver or oral liver extract, and parenteral crude liver extract, usually given intravenously (table 3). Because the more refined and concentrated liver extracts were not available when most of the patients were first seen, only 2 cases treated initially with such preparations are included in this series. However, for the past decade, refined liver extract given intramuscularly has been employed in the management of most of our new cases of pernicious anemia, and the results have been fully equal to those obtained with oral preparations and parenterally administered crude extracts. Some of these cases have been included in previous reports.^{8,9} No patients who received optimal therapy, regardless of type, suffered exacerbation of their neurologic manifestations.

In this series, there was no apparent difference over a long period of time, with respect to changes in the neurologic status, between those patients who received the recommended amount of therapy and whose blood values were consistently within normal limits, and those in whom treatment was irregular or was inadequate as judged by variations in erythrocyte count or morphology (table 4). In neither group was development of nervous system disease observed in patients who presented no manifestations of neurologic involvement when therapy was first instituted. The incidence and degree of improvement was about the same in the two groups. However, these observations require comment, and the conclusion that irregular or suboptimal therapy provides a safeguard against development of nervous system disease is not justifiable. In the first place, all of the patients received intensive initial therapy with apparent complete arrest of spinal cord degeneration. In the second, the fact that these patients returned frequently over a period of many years is evidence that they were cognizant of the importance of adequate follow-up examination and treatment, even though they at times neglected it. Recurrence of paresthesia or of mild symptoms of anemia was a warning to them to resume active therapy. In the third place, the severity of the neurologic process in the two groups is not comparable. Of the 11 patients with evidences of extensive spinal cord involvement, 10 are included in the optimal therapy group, justifying the inference that irregular or inadequate treatment seriously affects the chances for long time survival of patients with severe nervous system disease. On the other hand, it is worthy of note that no patients in the inadequately treated group with the milder degrees of involvement showed more than transient exacerbations of their neurologic manifestations.

The patients in this series who suffered definite hematologic relapse, as indicated by an erythrocyte count of less than 3,000,000 per cu. mm. with macrocytosis did not fare as badly as might have been expected. Eleven of this group were free of evidence of neural involvement when first seen, and only 4 of these developed neurologic manifestations during subsequent relapses. In each instance the lesion was classified as moderately severe (++) and was arrested with good functional improvement when intensive therapy was resumed. Of 8 patients presenting symptoms and signs of mild or moderate degree, only one suffered irreversible progression of spinal cord damage during hematologic relapse. Here also, it should be

emphasized that the relapses suffered by these patients were generally of short duration, that the series includes only those patients who were willing and able to return, and that no patient with pre-existing severe central nervous system disease who suffered hematologic relapse has been followed for as long as ten years

EXPERIENCES WITH FOLIC ACID

Since January, 1946, 15 patients with pernicious anemia have been treated with synthetic folic acid (pteroylglutamic acid) for sufficiently long periods to permit an evaluation of the early therapeutic results obtained with this material and a comparison of the results with those secured with other forms of treatment. Nine members of the group were males, 6, or 40 per cent, were without evidence of neuropathy, 5 had previously been under treatment for pernicious anemia, but only 1 had normal blood values at the time folic acid treatment was begun. The 6 patients without nervous system disease have all maintained normal blood values for one year or longer, while receiving 5 mg of folic acid by mouth daily, and none have developed neurologic manifestations *

REPORT OF CASES

One patient (H W) a man of 64, had paresthesias of the extremities, diminished knee and ankle jerks and impaired vibratory sense in the lower extremities when folic acid, 10 mg orally each day, was started during hematologic relapse. Within three months, coincident with restoration of blood values to normal, paresthesias had disappeared, and the patient had no complaints. A woman (T K), aged 69, had evidences of presumptive peripheral nerve and posterior column involvement with slight ataxia and impairment of sense of motion and position when the diagnosis of pernicious anemia was first made during hematologic relapse. On folic acid, 10 mg daily by mouth, there was significant functional and symptomatic improvement of moderate degree observed over a period of eight months. A man (C N), aged 76, had moderate involvement of the nervous system when first seen in 1938. He was treated with refined liver extract by intramuscular injection with marked (+++) improvement in his neurologic status. In April, 1946, his blood values were slightly abnormal, presumably due to too long intervals between treatments, and therapy was changed to folic acid, 10 mg daily by mouth, later reduced to 5 mg. There was no reactivation of the neurologic process at the time of institution of folic acid therapy, and none has occurred over a period of fourteen months. A woman (E C), 70 years old, was found to have pernicious anemia in 1938, with a moderately severe neural lesion. While under treatment with desiccated stomach, there was marked (+++) improvement in the neurologic manifestations. In May, 1946, treatment was changed to folic acid, 10 mg orally each day. After six months, there was no exacerbation of the neurologic process, but the erythrocyte level had declined to 3,600,000 per cu mm with a mean corpuscular volume of 105 cubic microns. Desiccated stomach, 20 Gm daily, was substituted for the folic acid and the blood values were rapidly restored to normal.

The 4 remaining patients with pernicious anemia in our folic acid treated series may be said to have had unsatisfactory results with respect to their neurologic status. In 2 of these, the adverse changes were slight and may have been equivocal, or the dosage, for these individuals, may have been too small. A physician (W F) was first found to have pernicious anemia in April 1946 and was treated initially with folic acid, 15 mg daily by intramuscular injection. His erythrocyte count was 2,600,000 per cu mm, and the maximum reticulocyte percentage, reached on the eighth day, was 15.6. He had troublesome paresthesia, especially in the toes, mild ataxia, impaired vibratory sense distal to the mid-tibiae, and swaying in the Romberg position. After one month on the parenteral 15 mg dosage, the patient felt much stronger, his appetite had improved, and he had gained weight, but there was no change in his neurogenic symp-

* Since this report was submitted, one of the patients developed severe paraplegia while receiving 10 mg of folic acid daily.

toms The erythrocyte count was 4,300,000 per cu mm and slight macrocytosis was still present At this time the dosage of folic acid was reduced to 5 mg orally each day Two months later the neurologic manifestations and the blood values were unchanged He was then given refined liver extract, 15 units intramuscularly, every three weeks, together with the daily oral dose of folic acid, 5 mg All neurogenic symptoms, except occasional slight tingling in the toes, disappeared within two months time, and the blood values have been entirely normal for one year A woman (B C), aged 51, was first seen and diagnosed as pernicious anemia in September, 1946 Anemia was minimal, the erythrocyte count being 3,900,000, but characteristic morphologic changes were present, and achlorhydria persisted after histamine injection There were manifestations of active, moderately severe, neurologic disease, chiefly paresthesia, ataxia, and deep sensory disturbances Folic acid orally, 10 mg daily, was given for two months There was no change in the blood values, and the patient stated that numbness and tingling had become more severe, although there was no demonstrable alteration in the neurologic signs Folic acid was discontinued, and refined liver extract, 15 units, was given intramuscularly, at first twice and later once weekly The blood values were entirely normal, and there was a moderate degree of relief of neurogenic symptoms one month later

In the other 2 remaining cases, there can be no doubt that spinal cord disease progressed actively while the patients were receiving reasonably large doses of folic acid One of these (J N) a man of 51 years, was found to have histamine refractory achlorhydria and atrophic gastritis by gastroscopic examination four years before the diagnosis of pernicious anemia was made At the earlier examination his complaints were limited to gastrointestinal disturbances, he had no glossitis, no anemia, and no symptoms referable to the nervous system In April 1946 he was admitted to another hospital where the diagnosis of pernicious anemia was made Symptoms of increasing fatigability, paresthesia of the hands and feet, and ataxia had been present for about six months Shortly before his admission, he developed pronounced mental changes characterized by depression, feelings of guilt, and religious preoccupation Details of the hematologic and neurologic examinations at the time of admission are not available, but it is known that the anemia was of moderate degree with an erythrocyte count of approximately 3,000,000 per cu mm The patient was able to walk unassisted, and there were no sphincter disturbances He received one or two injections of liver extract, and then was treated exclusively with folic acid, 20 mg by mouth daily There was symptomatic improvement with clarification of the mental status, and he was discharged after about one month in the hospital, in May, 1946 He continued to take folic acid in the above dosage at home, and the fact that he actually received the medication is attested by his wife who is an entirely reliable person, well known to us On June 14, 1946, he was first seen in the out-patient department of the Simpson Memorial Institute He walked alone, but with considerable ataxia, was oriented and responsive, and had no specific complaints other than paresthesia His erythrocyte count was 3,400,000 per cu mm, hemoglobin 11.9 grams per 100 cc, and hematocrit 35 per cent He was advised to continue taking folic acid, 20 mg daily On the morning of June 20 he was unable to leave his bed, and during the next two days he rapidly developed the signs of extremely severe spastic ataxic paraplegia with loss of sphincter control On June 22 he was admitted to the Simpson Memorial Institute Knee and ankle jerks were not obtained Plantar stimulation gave an extensor response bilaterally Vibratory sense was completely lost over the bones of the lower extremities and the crests of the ilium Sense of motion and position of the toes was absent The patient was unable to bear any weight on his legs and had no sense of floor resistance Folic acid was discontinued, and refined liver extract, 15 units, was given daily by intramuscular injection This dosage was continued until August 5, when it was reduced to 15 units, three times a week, until December 12, when it was changed to 15 units twice weekly Improvement of the neurologic status was slow but definite After six weeks he was able to use a walking device, and sphincter control had returned In four months he could get about with crutches, and nine months after the institution of liver extract therapy he discarded the crutches for canes At that time, March, 1947, the knee and ankle jerks had returned, the Babinski sign was no longer obtained, and vibratory sense was present, although diminished as far distal as the mid-tibiae Hematologic values were restored to normal within a few weeks after beginning liver therapy

The last case to be reported is that of a man (S K) of 55 years who was admitted to our service on July 12, 1946 His earliest symptom was impaired sense of taste (? olfactory disturbance) and anorexia which developed eleven months before his admission One month later he first noted numbness and tingling of the extremities and difficulty in walking His symptoms were very slowly progressive, and he

continued with his occupation as a merchant until his hospital admission. The initial red blood cell count was 3,600,000 per cu mm, hemoglobin 12.2 grams per 100 cc, hematocrit 36 per cent. Histamine refractory achlorhydria was present. The gait was ataxic, Romberg and Babinski signs were present, knee and ankle jerks were hyperactive bilaterally, vibratory sense was impaired to absent over the lower extremities, and sense of motion and position of the toes was disturbed but not completely lost. A diagnosis of pernicious anemia with moderately advanced postero-lateral column degeneration was made, and the patient was treated with folic acid, 10 mg intramuscularly daily. After ten days the oral route was substituted for the intramuscular mode of administration. The patient was discharged on July 28 and walked out of the hospital unassisted. He returned eleven days later, on August 9, unable to stand or walk alone and with complete loss of vibration and position sense in the lower extremities. The erythrocyte count at this time was 3,900,000 per cu mm, hemoglobin 14.6 grams per 100 cc, hematocrit 39 per cent. In place of folic acid he was given refined liver extract, 15 units intramuscularly daily for one week, then 15 units three times a week. He returned four weeks later, on September 9, showing some improvement, but unable to walk without assistance. At his next visit, after another interval of four weeks, he walked alone with the aid of a cane. On June 17, 1947, after ten months of liver extract therapy, he felt quite well and walked with only a slightly hesitant gait. Vibratory sense was apparently normal over the right lower extremity, but was diminished, although nowhere absent, over the left. There was return of sense of motion and position of the toes.

DISCUSSION

Experience in the management of cases of pernicious anemia during the early period of their treatment and over a number of years indicates that administration of sufficient amounts of desiccated stomach, whole liver, oral liver extract, and crude or refined liver extracts by parenteral routes, if accompanied by a hematologic response, will invariably lead to the arrest of the neurologic degenerative process and will usually be followed by a significant degree of symptomatic and functional improvement. Furthermore, if adequate treatment, as judged by consistently normal erythrocyte values, is taken continuously, exacerbation of nervous system disease will not occur. Even if treatment is irregular and suboptimal, provided there are no long periods of relapse, patients with less severe degrees of neurologic involvement will rarely suffer irreversible progression of their neural lesion. These statements are apparently not valid in the case of folic acid therapy. The occurrence and progression of combined system degeneration in patients with pernicious anemia under treatment with folic acid was first reported by Vilter, Vilter and Spies¹⁰ and by Meyer.¹¹ The phenomenon has also been noted by Heinle and Welsh¹² and by Hall and Watkins.¹³ In some of the cases reported, the activity of the process was not arrested when the dosage of folic acid was increased many times.

The failure of folic acid to control spinal cord disease in some cases may be taken as evidence that this vitamin corrects only a specific deficiency responsible for the hematopoietic disturbances occurring in pernicious anemia. This hypothesis, however, does not satisfactorily explain two types of observations which have been made by ourselves, as well as by others, namely, first, the fact that not all patients with pernicious anemia, in the absence of important complications, respond to folic acid by restoration of fully normal hematologic values, even when large doses of the vitamin are given by both oral and parenteral routes, and second, some patients experience definite relief of neurogenic symptoms while receiving folic acid. This improvement may be due primarily or entirely to peripheral nerve

recovery, but even so it may be said that such patients, over a period of many months, show no evidence of progress of nervous system involvement

The fairly uniform and predictable results of liver and stomach therapy in pernicious anemia and the variability of the responses of persons with this disease to administration of synthetic folic acid suggest that there is in pernicious anemia a widespread metabolic defect in which a number of interrelated factors or processes are involved, one of these being the ability to convert the naturally occurring conjugated form of folic acid to the free vitamin ¹⁴ ¹⁵ However, defective utilization of folic acid is not the only cause either of the hematopoietic or the neural disturbances. It appears, with some supportive evidence,¹⁴ that among the therapeutic properties of stomach and liver is included a corrective effect on the disordered metabolism of folic acid which is responsible, in part, for the manifestations of pernicious anemia

SUMMARY AND CONCLUSIONS

Seventy patients with pernicious anemia have been observed for periods of not less than ten years. The clinical course in these cases has been analyzed with particular reference to changes in the neurologic status

Most of the patients, whether treated with oral preparations of stomach or liver, or parenteral crude or refined liver extracts, showed significant improvement of their neurologic manifestations. The period of improvement was limited, essentially, to the first year of therapy

Thirty-six members of the series received treatment regularly and were maintained consistently in complete hematologic remission. Fifteen of the patients did not adhere to an optimal therapeutic regimen, and their blood values were frequently abnormal, although definite relapses did not occur. In the former group there were no instances of development or progression of neural lesions. In the latter such adverse changes as did occur were transient and reversible on resumption of adequate therapy. Nineteen patients in the series suffered clinical and hematologic relapses after their initial response to intensive therapy. The end results in this group were not so favorable, but nevertheless serious progression of spinal cord involvement was rarely observed. The apparent infrequent occurrence of pronounced changes is attributed to the short duration of the relapses and to the relatively mild degree of nervous system involvement present when the diagnosis of pernicious anemia was made. It may be assumed that patients with more extensive neural disease who suffered relapses, progressed to a fatal termination

The observations reported in no way justify the conclusion that irregular or suboptimal therapy is without serious risk. They are presented in order to indicate what the long-term clinical results may be in the case of patients with pernicious anemia, who frequently fail to adhere to an ideal therapeutic regimen

The early results of treatment with synthetic folic acid, as observed in a series of 15 patients, indicate that both the hematologic and neurologic response to this form of therapy is much less predictable than is the case with stomach or liver preparations. It is suggested that disturbance of folic acid metabolism is not the sole cause of either the hematologic or the neurologic manifestations of pernicious

57431

anemia, but that inability to utilize folic acid effectively may play a part in the development of both myeloid and neural abnormalities

THE DEVELOPMENT AND PROGRESSION OF SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD IN PATIENTS WITH PERNICIOUS ANEMIA TREATED WITH SYNTHETIC PTEROYLGLUTAMIC (FOLIC) ACID

By J F ROSS, M D *, H BILDING, M D , AND B L PAEGEL, M D

THE ISOLATION, identification and synthesis of folic acid (pteroylglutamic acid) have provided an extremely potent hematopoietic agent.¹ Unquestionably folic acid induces hematologic remissions in patients with pernicious anemia. Evidence is accumulating that indicates its ineffectiveness in preventing the development or progression of subacute combined degeneration of the spinal cord. Furthermore, it is not certain that normal blood levels can be maintained for prolonged periods of time in patients treated with folic acid alone.

During the last seventeen months we have substituted synthetic folic acid† for liver extract in the treatment of 22 patients with pernicious anemia. These cases have been observed with extreme care for evidences of development or progression of neurologic complications and for changes in hematologic or clinical status. During this brief period of time significant changes have developed in many of these patients that make advisable a report of our observations at the present time.

METHOD OF STUDY

CLINICAL MATERIAL

The diagnosis in each case was established by the demonstration of a macrocytic hyperchromic anemia with an associated leucopenia and thrombocytopenia, a histamine-refractory gastric achlorhydria and a response to liver extract or to folic acid with reticulocytosis and restoration of normal blood values. In many cases a megaloblastic bone marrow typical of pernicious anemia was demonstrated before treatment was started. Four patients were in hematologic relapse and were hospitalized during the initial period of study. Two of these patients previously had been seen in hematologic relapse, and remission had been induced with liver extract. It has been possible to compare their responses to folic acid with those previously obtained with liver extract. One patient in relapse had severe active subacute combined degeneration of the spinal cord.

The patients in remission had been known to have pernicious anemia for periods ranging from one to nineteen years and had been treated with liver extract in the Outpatient Department of the Massachusetts Memorial Hospitals before the beginning of this study. Six of these patients had evidence of subacute combined degeneration as manifested by paresthesias, diminution of vibration sense or reflex changes at the beginning of the study, but in all these cases the disease had been arrested and the signs had been unchanged for several years. Liver extract therapy was stopped at the beginning of this study. There was no restriction of diet, which was considered to be adequate in all patients. Eleven patients were taking supplementary vitamins or yeast, and these were allowed to continue this medication during the period of study. Folic acid was administered orally in 16 cases in doses ranging from 1.25 to 15.0 mg daily. Six patients received 30 to 100 mg by intramuscular injection once every four weeks.

From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine, Boston.

* Formerly Welch Fellow in Internal Medicine of the National Research Council. A portion of this investigation was carried out while under tenure of the Welch Fellowship.

† The synthetic folic acid (pteroylglutamic acid) used in this study was kindly furnished by Dr Stanton M. Hardy of the Lederle Laboratories, Inc., Pearl River, N. Y.

All the patients were seen at least monthly in the Outpatient Department of the Massachusetts Memorial Hospitals and when it became evident that neurologic symptoms were developing they were seen at weekly or semiweekly intervals. Careful neurologic and hematologic studies were performed at each visit.

TECHNICAL METHODS

Blood studies were performed on venous blood placed in mixed ammonium and potassium oxalate.² Hemoglobin determinations were done on photoelectric colorimeters by the oxyhemoglobin method.³ Hematocrits were determined with Wintrobe tubes, with centrifuging for one hour at a relative centrifugal force of 1800. Erythrocyte and leucocyte counts were made in duplicate and averaged. Erythrocyte indices were calculated by the method of Wintrobe. Direct platelet counts were made with Rees-Ecker diluting fluid. Reticulocyte counts were made on blood films prepared from a mixture of venous blood with 0.3 per cent cresyl blue and 0.6 per cent solution of sodium chloride. Films of bone marrow obtained by sternal aspiration were stained with Wright's and Giemsa's stain.

OBSERVATIONS

PERNICIOUS ANEMIA IN RELAPSE

Four patients were in severe hematologic relapse when folic acid therapy was started. Of these, 2 had never before had antianemia therapy, 1 was in relapse subsequent to three years without liver extract therapy, and 1 was in relapse following a low maintenance dose of folic acid. The courses of these 4 patients are typical of the responses that may be produced with folic acid, and brief case histories are presented.

CASE I

Pernicious anemia in severe hematologic relapse. Remission induced with orally administered folic acid. Gradual development of anemia and subacute combined degeneration of the spinal cord after one year of maintenance on folic acid.

J B, a 65 year old white man, was admitted to the hospital in May, 1946, with a history of easy fatigability for two years and marked weakness and anorexia for two weeks. Physical examination revealed pallor of the skin and mucous membranes, a red tongue with atrophy of the lateral papillae, hypoactive deep tendon reflexes in the lower extremities and slightly diminished vibration sense in the feet. Blood studies showed a severe macrocytic anemia, leucopenia and thrombocytopenia (table 1 and fig 1), and the sternal bone marrow was characteristic of pernicious anemia in relapse. There was histamine refractory gastric achlorhydria. Folic acid therapy, 15 mg daily by mouth, was started at this time. Weakness and anorexia were noticeably lessened on the second day of therapy and the patient was completely asymptomatic at the end of the second week. In one month's time the physical findings were normal and there was full recovery of vibration sensation. A maximum reticulocyte response of 2.9 per cent was reached on the eighth day of therapy. Just prior to the rise in reticulocytes a substantial increase in the white cell and platelet counts was noted. A steady increase in the red cell count and hemoglobin began after the fourth day. Normal blood levels and red cell indices were present by the third month and were maintained until the eighth month, when the red cell count, hematocrit and hemoglobin began to fall. By the twelfth month the patient showed a definite anemia.

With the exception of occasional slight glossitis the patient remained asymptomatic during the first eleven months of folic acid therapy. Beginning with the seventh month there was gradually progressing diminution in vibration sense, although position sense and motion sense were normal and Romberg's sign was negative. In the twelfth month the patient began to experience stiffness of the feet and numbness of the fingers. His gait became unsteady, particularly in the evening, and he staggered when he attempted to walk in the dark. Knee and ankle jerks were markedly hypoactive at this time, vibration sense was

impaired below the knees, and motion sense was diminished in the toes. The patient swayed slightly in the Romberg position and staggered when he tried to walk with his eyes closed.

Comment This previously untreated case of pernicious anemia showed early and rapid clinical and hematologic improvement in response to 15 mg of folic acid given daily by mouth. The reticulocytosis of 29 per cent in response to folic acid therapy was slightly less than the 37 per cent expected optimum response to liver extract, but the rate of regeneration of erythrocytes, leucocytes and platelets was fully as rapid as would have been expected with liver extract therapy. The blood remained normal for eight months but subsequently fell to anemic levels. Definite subjective and objective signs of subacute combined degeneration appeared during the twelfth month of folic acid therapy.

FIG 1 (Case 1) Previously untreated pernicious anemia in relapse. Remission induced with orally administered folic acid. Gradually developing anemia and subacute combined degeneration after 7 months of folic acid therapy.

CASE 2

Pernicious anemia with mild anemia but severe subacute combined degeneration. No improvement in neurologic status after twenty-five days of orally administered folic acid.

A W, a 60 year old white woman, was admitted to the hospital with a history of increasing paresthesias in all extremities, weakness, anorexia and weight loss of one year's duration. The significant physical findings were slight atrophy of the lateral lingual papillae, hyperactive deep tendon reflexes, a positive Romberg's sign, a slightly ataxic, spastic wide-based gait, marked diminution of vibration sense in the knees, ankles, toes and fingers and some impairment of position sense in the fingers. The red cell count was 3,000,000, the hemoglobin 12.8 Gm per 100 cc, the mean corpuscular volume 122 cubic micra, and the white cell count 5700. There was histamine-refractory gastric achlorhydria. Folic acid was administered orally in a daily dose of 15 mg throughout the twenty days of hospitalization. The reticulocytes rose from 2.1 to 5.8 per cent on the seventh day. At discharge the red cell count was 3,410,000, the hemoglobin 13.9 Gm per 100 cc, and the white cell count 8275. After one week during which the

folic acid dosage was increased to 45 mg daily the red cell count was 3,540,000 and the hemoglobin 14 Gm per 100 cc

After twenty-eight days of folic acid therapy paresthesias and weakness persisted unchanged, and there was no improvement in the signs of subacute combined degeneration of the spinal cord. Daily intramuscular injections of 15 units of purified liver extract were begun and continued during the next five weeks. Subjective improvement and a decrease in paresthesias occurred in response to this therapy, but further neurologic examinations could not be performed. A blood study performed after two months of folic acid therapy and thirty-eight days of liver extract therapy showed a normal hemoglobin and hematocrit but persistent marked macrocytosis (table 1)

Comment This previously untreated patient had a moderate, although markedly macrocytic, anemia but severe subacute combined degeneration of the spinal cord. She had a submaximal reticulocyte response to folic acid (only 5.8 per cent as compared with an anticipated 12.0 per cent), and the blood levels rose very slowly even after liver extract therapy was given in addition to an increased dosage of folic acid. There was no subjective or objective evidence of improvement of the subacute combined degeneration during twenty-eight days of folic acid treatment, and it was not possible to follow the patient adequately for a longer period of time.

CASE 3

Pernicious anemia in relapse, remission induced with orally administered folic acid. Subacute combined degeneration and mild anemia developing after sixteen months of maintenance therapy with folic acid. Progression of subacute combined degeneration after institution of liver extract therapy while folic acid was continued.

H. C., a 59 year old white woman, was first admitted to the hospital in December, 1940, with weakness, glossitis, anorexia and weight loss of two years duration. Physical examination revealed marked pallor of the skin and mucous membranes, atrophy of the lingual papillae, moderate glossitis, a palpable liver and diminished vibration sense below the knees. There was a severe macrocytic anemia and a megaloblastic bone marrow (table 1 and fig. 2). Histamine-refractory gastric achlorhydria was present. In response to 15 units of liver extract administered intramuscularly daily, there was a rise in reticulocytes to 14.6 per cent. After one month of therapy the red cell count was 4,330,000 and red cell indices were essentially normal. Therapy was gradually reduced to 15 units of liver extract a month. Blood values continued to rise and throughout the ensuing seventeen months were optimal.

Except for the occasional ingestion of cooked liver the patient lapsed in therapy from September, 1942, to January, 1946, when she was readmitted to the hospital with recurrence of the original symptoms and paresthesias of the hands and feet. The significant physical findings were pallor of the skin and mucous membranes, atrophy of the lateral lingual papillae, a slightly unsteady gait, hyperactive knee jerks, absent ankle jerks and a moderate decrease in vibration sense below the knees. The blood and bone marrow were characteristic of pernicious anemia in relapse (table 1 and fig. 2). The patient was given 15 mg of folic acid by mouth daily, and a maximum reticulocyte response of 11.8 per cent was obtained on the sixth day of therapy. She rapidly became asymptomatic, and after one month of treatment the red cell count and hemoglobin had risen to moderate levels with a decrease in macrocytosis. There was no change in neurologic status at that time. Folic acid therapy (15 mg by mouth daily) was continued after discharge in February, 1946. One month later the patient was readmitted for treatment of a myocardial infarction and pyelitis. Vibration sense in the ankles and toes was diminished. The blood values were unchanged. The dosage of folic acid was increased to 100 mg daily, by mouth for five days and then intravenously for the next ten days. This increased dose produced no improvement in the blood picture, and the original dosage of 15 mg daily by mouth was resumed. Nineteen days later this was supplemented by daily intramuscular injections of 15 units of liver extract for twelve days. This resulted in symptomatic improvement, relief of the glossitis and improvement in vibration sense in the ankles and toes, but no

further hematologic response. During the subsequent two months on folic acid therapy alone the red cell count and hemoglobin rose to fairly satisfactory levels and the red cell indices became normal. Vibration sense was fully recovered. During the ensuing ten months there was a gradual decrease of the red cell and hemoglobin levels and a return of macrocytosis.

In the sixteenth month of folic acid treatment and twelve months after the last injection of liver extract, the patient complained of steadily increasing numbness of the hands, forearms and feet. Her family stated that she became extremely forgetful and irritable. There was a rapid and progressive loss of vibration sense in the lower extremities and impairment of position and motion sense in the toes and fingers. Liver extract therapy was started, 75 units being given first semiweekly and then weekly, and folic acid medication was continued. In spite of the injection of 260 units of liver extract during the next six weeks the symptoms and signs of subacute combined degeneration of the spinal cord progressed. At the end of this period folic acid therapy was discontinued.

FIG. 2 (Case 3) Pernicious anemia with comparable remissions induced on different occasions with liver extract and with folic acid. Suboptimal response to oral folic acid not improved by large doses of folic acid administered intravenously or by liver extract. Progression of subacute combined degeneration 12 months after last injection of liver extract.

Comment This case provides an interesting comparison of the relative effectiveness of folic acid and liver extract in inducing remission in pernicious anemia. Symptomatic improvement occurred earlier and was more marked with liver extract than with folic acid therapy. The reticulocyte response to both liver extract and folic acid was submaximal. The rate of increase in the red cell count in response to folic acid was slower than had occurred previously with liver extract, but the hematologic response probably was hampered by the complicating myocardial infarction and pyleitis. In the face of these complications neither an increase in the dosage of folic acid nor a course of liver extract therapy was effective in improving the blood picture. Following recovery from these illnesses the blood levels temporarily rose to normal. The optimal levels previously maintained with liver extract therapy never were observed during folic acid treatment, and a gradual diminution of blood levels occurred during the last ten months of therapy. Subacute combined de-

generation became apparent in the sixteenth month of folic acid therapy, twelve months after the last injection of liver extract, and neurologic disease progressed during the next six weeks in spite of the injection of 260 units of liver extract

CASE 22

Hematologic relapse on 30 mg of folic acid administered once monthly by injection Remission on 15 mg of folic acid daily by mouth Subsequent explosive development of severe subacute combined degeneration of the spinal cord

J S, a 69 year old white man, had been treated for pernicious anemia with liver extract by a private physician in 1938, and was first admitted to the hospital in 1939 with a history of weakness and anorexia following a six months lapse in therapy Blood studies showed a severe macrocytic anemia (table 1 and

Fig 3 (Case 22) Relapse of pernicious anemia while receiving 30 units of folic acid by intramuscular injection once each month Remission induced with 15 mg of folic acid daily by mouth comparable with remission induced with liver extract on previous occasions Rapid development and progression of subacute combined degeneration on folic acid maintenance therapy while blood was normal

fig 3) The patient responded to liver extract therapy with a reticulocyte response of 20.9 per cent on the sixth day of therapy, and normal blood levels were attained by the third month In 1942 the patient again lapsed in therapy and underwent a second hematologic relapse He again showed an adequate response to liver extract Since 1943 adequate blood levels were maintained with intramuscular injection of 30 units of liver extract monthly The patient ingested daily 10-15 Gm of yeast during the entire period of the subsequent study, a fact that should exclude vitamin deficiency as a contributing factor Folic acid was substituted for liver extract in June, 1946, and 30 mg of folic acid once each month was given by intramuscular injection At this time the patient was completely asymptomatic, physical examination was essentially negative, and neurologic examination was entirely negative The blood levels were suboptimal, with a moderate degree of macrocytosis (table 1 and fig 3) There was a persistent drop in the red cell and hemoglobin levels, and by the fifth month the patient showed a marked macrocytic anemia Weakness and dyspnea appeared during the third month, but the only abnormal physical finding was marked pallor of the skin and mucous membranes Neurologic examination was completely negative At this time therapy was changed to a daily oral dose of 5 mg of folic acid Symptoms of anemia increased,

and there was a further decrease in blood levels during the next week. The dosage of folic acid was increased to 15 mg a day by mouth. Rapid symptomatic and hematologic improvement followed, and in two months the red cell count returned to its original pre-folic acid level. A reticulocyte response of 63 per cent was noted on the seventh day, but since these counts were performed only at weekly intervals the maximum reticulocytosis probably was not detected. Neurologic examination at this time was negative.

Eight and one-half months after folic acid had been substituted for liver extract, three months after the start of oral folic acid therapy and one month after restoration of normal blood levels, the patient complained of heaviness in the soles of his feet and stated that he felt muscle-bound in the calves and thighs. The only neurologic abnormality at this time was slightly diminished vibration sensation in the toes. One week later his hands and feet felt 'like blocks of wood' and there were periodic episodes of a burning sensation from the toes to the hips. At this time the patient began to need assistance in maintaining his balance, and soon he was unable to walk without considerable aid. Within another two weeks he was unable to stand or walk and could not feed himself because of incoordination of the hands.

On admission to the hospital the general physical examination, complete blood studies and sternal bone marrow examination yielded normal findings. The patient's mental status and speech were normal. Examination of the cranial nerves showed impairment in the first (inability to recognize the smell of coffee, vanilla or wintergreen) and the second (moderate bilateral diminution in visual acuity and moderate constriction of visual fields), although the optic fundi were not remarkable. The remaining cranial nerves were intact. There was no gross inequality in muscular volume or power, but there was a definite increase in muscle tone, spastic in type, of the arms and legs. Coordination was extremely poor, and the patient was unable to hold objects or to feed himself. There was astereognosis, even for large objects, and marked past pointing in both arms. The heel-to shin test was poorly done. Romberg's sign was positive, and the gait, even with assistance, was spastic, slapping and staggering. Deep tendon reflexes in the lower extremities were markedly hyperactive, more so on the left than on the right. The Babinski response was present on the left and there was no response to plantar stimulation on the right. Abdominal and cremasteric reflexes were absent. Vibration sense was entirely absent below the tenth thoracic segment and in both hands, wrists and elbows. Position and motion sense were impaired generally, most markedly in the fingers, toes and ankles. There was loss of light-touch sensation over the ulnar side of both hands and on the medial aspect of the right foot. There was irregular patchy diminution of pain and temperature sensation in both arms and both legs, and decrease in sweating of both lower extremities and complete absence of sweating from the level of the knees downward. There was no interference with bladder or bowel function, however, and no change in sexual function (the patient had been impotent for 10 years). A lumbar puncture yielded normal spinal fluid.

Injection of 105 units of concentrated liver extract (15 units per cubic centimeter) was given intramuscularly daily for the next five weeks, and the administration of 15 mg of folic acid daily by mouth was continued. During this period there was gradual subjective improvement, beginning on the eleventh day. The patient gradually regained the coordinated use of his hands and feet, and after three weeks of liver extract therapy he was able to feed himself and to walk unassisted and without staggering, although the gait was still spastic and slapping. He was discharged from the hospital at the end of five weeks, at which time he felt well except for some residual numbness of the hands and feet and stiffness of the knees. Coordination of movement was normal, but the gait showed slight slapping. During the period of hospitalization the pattern of neurologic improvement was striking. First there was a decrease in the signs of lateral column disease: muscle tone returned to normal, deep tendon reflexes became less hyperactive, the plantar responses became flexor, and there was a gain in strength. With this improvement the patient was able to walk and to feed himself, even though the posterior column signs still persisted. Position sense was slightly improved in the fifth week of liver extract therapy, but there was no return of vibration sense.

Following discharge the patient was given 75 units of liver extract intramuscularly once a week and the dosage of 15 mg of folic acid daily was continued. There was only slight improvement in position sense during the next three weeks, no improvement in vibration sense, and persistence of paresthesias. Folic acid was discontinued after two months of liver extract therapy. Two weeks later position sense was practically normal, vibration sense perception began to return, and the hands and feet felt much less numb and nearly normal.

Comment This patient gradually developed a hematologic relapse over a six month period during which treatment consisted of 30 mg of folic acid by injection once a month. The rate of development and the severity of the hematologic relapse were comparable to two previous relapses that occurred following omission of liver extract. This indicates that folic acid in the amount given had no effect in maintaining remission. The hematologic response to 15 mg of folic acid taken orally each day was excellent and was comparable with the response obtained on two previous occasions with liver extract.

The most striking features of this case were the explosive development of extremely severe subacute combined degeneration after nine months of folic acid therapy and its appearance at a time when the peripheral blood picture and bone marrow were normal. Improvement of symptoms and signs of lateral column disease occurred gradually following the addition of liver extract therapy, but vibration sense and numbness of the hands and feet improved only after discontinuation of folic acid.

The clinical and hematologic responses of 3 cases to folic acid therapy were excellent and quite comparable to those that would have been expected with optimum liver extract therapy. Indeed, in Case 22 the rate of blood regeneration under folic acid therapy almost exactly paralleled that previously obtained with liver extract (fig 3). The reticulocyte responses were slightly less than would have been expected with liver extract, but were quite adequate in all 3 cases. Increases in white cell and platelet counts were marked and rapid. In Case 2 the degree of anemia was not severe, and consequently the rate of blood regeneration was not rapid. The suboptimal blood levels eventually obtained in Case 3 were not improved by additional liver extract therapy and probably are a reflection of the complicating cardiac disease and pyelonephritis.

Cases 1, 3 and 22 showed improvement in the sense of well-being on the third or fourth day following the beginning of folic acid therapy. This improvement was neither so striking nor so marked as that usually seen following the exhibition of liver extract. Glossitis was present in Cases 1, 3 and 22 and improved very slowly under folic acid treatment. In Case 1 it occasionally recurred during the period of maintenance therapy.

The extremely marked signs of subacute combined degeneration in Case 2 showed no improvement during the twenty-eight days of folic acid therapy, but they did not progress. The numbness and slight diminution of vibration sense initially present in Cases 1 and 3 gradually improved over a period of several months with folic acid therapy but recurred again after a year's treatment. Case 22 showed no neurologic abnormality at the time of hematologic relapse, and it was not until three months later, at a time when the blood picture was normal, that the patient developed extremely severe and rapidly progressive subacute combined degeneration of the spinal cord.

MAINTENANCE THERAPY OF PERNICIOUS ANEMIA IN REMISSION

Twenty-one patients with pernicious anemia in remission have been maintained on folic acid therapy for periods ranging from eight to seventeen months. In 19

TABLE 1—Continued

[illegible]

[illegible]

TABLE 1, ADDITIONAL REMARKS

- Case 1* Rapid remission induced Maximum reticulocytosis of 29% on 8th day Blood declined to sub-normal levels after 6th month Probable development of mild S C D beginning in 7th month
- Case 2* Mild anemia but marked macrocytosis Maximum reticulocytosis of 58% on 7th day Slight improvement in blood during 28 days of folic acid therapy Normal hemoglobin level but persistent macrocytosis following liver extract therapy No improvement in S C D with folic acid therapy
- Case 3* Response to folic acid comparable with response to liver extract 5 years previously Maximum reticulocytosis 118% on 6th day Suboptimal blood levels, not improved with liver extract, probably because of complicating disease Evidence of S C D at 16 months Rapid progression of S C D in spite of institution of liver extract therapy during continuation of folic acid
- Case 4* Blood levels higher and macrocytosis less than when under liver extract therapy S C D beginning in 11th month and progressing rapidly in spite of liver extract therapy while folic acid continued
- Case 5* For 8 months blood levels much higher than with liver extract therapy Moderate decrease after 8th month No definite evidence of S C D
- Case 6* Blood levels decreased at 8 months No evidence of S C D
- Case 7* Blood levels improved initially Subsequently decreased and fluctuated in fashion similar to that observed during liver extract therapy No evidence of S C D
- Case 8* Blood levels same as with liver extract therapy Probable development of early S C D
- Case 9* For 8 months blood levels much higher than with liver extract Then gradual decrease to initial levels No evidence of S C D
- Case 10* Blood levels initially higher than with liver extract, subsequent decrease Definite development of S C D
- Case 11* Blood levels same as with liver extract No change in S C D
- Case 12* Blood levels better than those maintained with liver extract Progression of S C D
- Case 13* Blood improved initially, but decreased to previous levels in 10th month Definite progression of S C D in 12th month
- Case 14* Blood levels unchanged even after increase in folic acid dosage S C D developed at 9½ months Progressed rapidly when folic acid dosage increased to 15 mg Continued progression of S C D after institution of liver extract while folic acid continued
- Case 15* Blood unchanged Signs of S C D appeared in 7th month and progressed in spite of increased folic acid dose
- Case 16* Blood unchanged No evidence of S C D
- Case 17* Decrease in blood levels during period of monthly injections Slight improvement on daily oral dose of folic acid Evidence of S C D appeared in 2nd month and progressed in spite of increased dose of folic acid
- Case 18* Temporary decrease in macrocytosis No evidence of S C D in spite of very low dose of folic acid
- Case 19* Transient increase in blood levels No evidence of S C D Died of heart failure in 11th month
- Case 20* Blood levels comparable with those maintained with liver extract Patient required 11 months to relapse after omission of liver extract on a previous occasion No S C D
- Case 21* Blood levels comparable with those maintained with liver extract therapy Improved with oral folic acid therapy No S C D
- Case 22* Hematologic relapse during monthly injections Remission induced with oral folic acid Rapid onset and progression of S C D when blood was normal Very gradual and incomplete improvement with liver extract therapy while folic acid continued More rapid improvement after omission of folic acid

patients (including Case 22, previously described) the clinical and hematologic aspects of the disease had been well controlled with liver extract for from one to nineteen years prior to the substitution of folic acid therapy In 2 patients (Cases 1 and 3) folic acid-induced remissions preceded maintenance therapy This group has

been subdivided according to the maintenance dose of folic acid administered (table 2) An increase in dosage was made in 8 patients during the latter half of the period of observation, and specific reference to these changes will be made The hemato-

*Figures preceded by # are numbers of cases listed in Table 1

logic and clinical data before and during folic acid therapy are presented in tables 1 and 2

Oral maintenance dose of 15 mg daily Five patients (Cases 1, 3, 4, 5 and 6) were given a daily oral maintenance dose of 15 mg of folic acid With the exception of 1 patient (Case 6) who was treated for only eight months, these patients remained on the same dosage schedule for twelve months Satisfactory blood levels were ob-

served early in the course of treatment in all 5 patients, and 1 patient (Case 4) consistently maintained higher levels with folic acid than he did with liver extract. A decline in the red cell count and hemoglobin to suboptimal levels began after the fourth and sixth month, respectively, in 2 patients (Cases 1 and 3) in whom remission had been induced with folic acid. A similar drop in blood levels was not observed in the other 2 patients (Cases 5 and 6) until the eighth month. In 1 patient (Case 3) a significant macrocytosis developed concomitantly with the decline in blood levels.

All 5 patients felt extremely well and were asymptomatic during the first eight to eleven months of treatment. In the twelfth month of therapy definite signs of neurologic disease appeared in Case 1 (see case report). In Case 3, in the sixteenth month of folic acid therapy and twelve months after the completion of a supplementary course of liver extract therapy, the patient developed the symptoms and signs of neurologic disease (see case report).

In Case 4 there had been mild but quiescent subacute combined degeneration for at least eight years, and there was no change in this condition during the first ten months of folic acid therapy. Beginning in the eleventh month, however, the patient developed paresthesias of the hands and feet and weakness and stiffness of the legs. His family stated that he became very irritable and occasionally wept because of anger. By the twelfth month these symptoms were worse and there was unsteadiness of gait and difficulty in walking. Knee jerks were increased, and vibration sense was decreased at and below the iliac crests. Liver extract was started in addition to continuation of folic acid, but in spite of the injection of 260 units in the next three weeks there was rapid progression of neural disease. By the end of this time the patient was unable to walk because of weakness of the legs and unsteadiness of gait. He complained of warmth of the hands and feet. He showed increased muscle tone in the legs, markedly hyperactive knee jerks, absent left ankle jerk and decreased right ankle jerk, a positive Babinski sign on the left and normal plantar response on the right. Position and motion sense of the toes was poor. The heel-to-knee test was poorly performed. Vibration sense was absent below the iliac crest. Romberg's sign was markedly positive. Folic acid was discontinued and the patient was hospitalized. A lumbar puncture yielded normal fluid.

This patient developed progression of subacute combined degeneration during folic acid therapy, which proceeded rapidly in spite of parenteral injection of large amounts of liver.

Oral maintenance dose of 10 mg daily. Two patients (Cases 7 and 8) were given 10 mg of folic acid daily for a period of twelve months. Case 8 maintained constant blood levels. Case 7 showed an initial improvement in red cell count and hemoglobin but a persistent macrocytosis, and the blood subsequently returned to levels essentially similar to those observed during liver extract treatment.

In Case 8 progressive diminution of vibration sense in the lower extremities and fingers appeared during the eleventh month, and in the twelfth month Romberg's sign became positive.

Oral maintenance dose of 5 mg daily. Two patients (Cases 9 and 10) were maintained on 5 mg of oral folic acid daily for twelve months. In both patients there was an

initial increase in the red cells and hemoglobin and a decrease in macrocytosis, but in the eleventh and twelfth months the red cell count and hemoglobin returned to pre-folic acid values, and in Case 9 there was recurrence of macrocytosis

Subjective improvement and an increase in appetite were noted by each patient with beginning of folic acid therapy, and these continued throughout the period of observation. Case 9 remained asymptomatic and maintained a normal neurologic system during the period of observation. Paresthesias and diminution in vibration sense appeared in Case 10 in the eleventh month. By the twelfth month there was marked diminution of vibration sense in the toes and ankles, a positive Romberg's sign, a slightly unsteady gait, hypoactive knee and ankle jerks and a positive Babinski's sign

Oral maintenance dose of 2.5 mg daily Only one patient (Case 11) was given a daily oral dose of 2.5 mg of folic acid. This patient maintained as high blood levels throughout the eleven months of treatment as she had previously done with large doses of liver extract. She remained asymptomatic and showed no change in her neurologic signs of minimal subacute combined degeneration of the spinal cord

Oral maintenance dose of 1.25 mg daily Five patients (Cases 12-16) were given daily doses of 1.25 mg of folic acid by mouth. This dosage was increased to 15 mg daily in 3 patients (Cases 13, 14 and 15) in approximately the tenth month of treatment. With the exception of Case 16, who was observed for only eight months, the members of this group remained on folic acid for eleven, twelve or thirteen months. The blood picture of 3 of these patients was comparable to that previously maintained by them on liver extract. In Case 12 the blood levels were better, and in Case 13 there was a temporary increase in red cells and hemoglobin and a decrease in macrocytosis, which persisted for eight months and then returned to the levels previously maintained with liver extract

Two of these patients (Cases 12 and 13) had subacute combined degeneration of the spinal cord at the time folic acid therapy was started, but in both the disease had remained stationary for several years under liver extract therapy. In Case 12 progression of neural disease was shown during the twelfth month of folic acid therapy. Weakness and stiffness of the legs, numbness of the feet, unsteadiness in gait and swaying on Romberg's test became definitely severer at this time and led to institution of liver extract therapy. In Case 13 the patient complained of a squeezing sensation in the feet and calves, and there was a definite decrease in vibration sense below the level of the iliac crests and a markedly positive Romberg's sign during the twelfth month of therapy

After nine and one-half months of folic acid treatment the patient in Case 14 showed development of subacute combined degeneration. The dosage of folic acid was increased to 15 mg daily by mouth for the next six weeks, but the signs of neurologic disease progressed even more rapidly. By the eleventh month of maintenance therapy the patient exhibited weakness of the entire body and a numbness and tingling of the hands and feet. Knee and ankle jerks were extremely hyperactive, vibration sense was markedly impaired below the iliac crests and was entirely absent in the left leg. An injection of 75 units of liver extract was given, which produced only minimal improvement in one week's time. Folic acid was

omitted and 45 units of liver extract were given each week for the ensuing two weeks. Two weeks after discontinuance of folic acid there was marked subjective improvement, Romberg's sign was negative, and vibration sense was improved. There was strikingly rapid progression of neural disease during folic acid treatment, and significant improvement did not occur in spite of liver extract therapy until folic acid was discontinued.

Of the 2 other patients without subacute combined degeneration at the beginning of folic acid therapy, Case 16 remained asymptomatic and developed no abnormal neurologic signs during the eight months that she was observed. Case 15, however, showed progressive diminution of vibration sense from the seventh to twelfth month. An increase in folic acid to 15 mg daily at nine and one-half months failed to prevent progressive diminution of vibration sense or the development of hypoaffective knee jerks.

Maintenance therapy with monthly intramuscular injections. The remaining 6 patients (Cases 17-22) were given intramuscular injections of folic acid once a month. None of these patients had evidence of subacute combined degeneration at the time folic acid therapy was started. The doses administered were 100 mg (Cases 17, 18 and 19), 40 mg (Case 20) and 30 mg (Cases 21 and 22). With one exception (Case 19), oral folic acid therapy (1.25 to 15.0 mg daily) was substituted for injected folic acid in these patients between the fifth and ninth month of observation. The members of this group remained on folic acid for periods of ten to twelve months.

Of the 3 patients receiving 100 mg of folic acid monthly, 2 (Cases 18 and 19) showed an initial rise in blood levels with a subsequent decrease to the original levels. The blood levels of the other patient (Case 17) dropped slightly, but returned to the original suboptimal levels after substitution of a daily oral dose of 15 mg of folic acid.

This latter patient began to show paresthesias and diminution of vibration sense after the second month of therapy. The paresthesias decreased slightly following the administration, from the fifth month onward, of 15 Gm of Brewer's yeast daily. Daily oral doses of 1.25 mg of folic acid were substituted for the monthly intramuscular injections in the sixth month, and this dosage was increased to 15 mg daily in the tenth month. All these measures failed to halt progressive diminution of vibration sense. By the eleventh month there was marked diminution of vibration sense in both lower extremities. Motion and position sense were impaired in the toes, and Romberg's sign was positive. Case 18 remained asymptomatic and was placed on a daily oral dose of 1.25 mg of folic acid in the ninth month. In Case 19 there was no evidence of neurologic disease, but the patient died of congestive heart failure during the eleventh month.

One of the 3 patients on maintenance therapy of 30-40 mg monthly (Case 22) experienced a hematologic relapse within six months (see case report). A satisfactory hematologic remission was produced when orally administered folic acid was substituted for the monthly injections. The other 2 patients showed persistent macrocytosis, although their blood levels were comparable with those previously maintained with liver extract therapy. A moderate improvement in blood levels and a decrease in macrocytosis was observed in Case 21 after the substitution of a

daily oral dose of 1.25 mg of folic acid, but no change in the blood picture in Case 20 followed such substitution

In Cases 20 and 21 the patients remained asymptomatic and showed no evidence of neurologic damage throughout the period of folic acid therapy. As described previously, the patient in Case 22 exhibited an explosive development of spinal cord disease during the eighth month of observation, despite a normal blood and bone marrow

DISCUSSION

HEMATOLOGIC ASPECTS

Induction of Remission Orally administered folic acid induced hematologic remissions that were comparable in rate and completeness with those that would have been predicted in response to liver extract therapy. Reticulocyte responses to folic acid were less marked and subjective improvement was not so sudden in onset or so marked as usually follows exhibition of liver extract. Glossitis was not so rapidly or so completely relieved, and tended to recur in mild form during folic acid therapy.

Maintenance Therapy When folic acid was substituted for liver extract the majority of the patients showed a transitory but significant increase in blood levels and a decrease in mean corpuscular volume. This initial but unsustained improvement may have been due to the combined effect of folic acid and liver extract, since the latter is stored in the body and may continue to exert its hematopoietic effect for many months after its injection.^{4, 5}

These observations might be taken to suggest that the patients had not received optimal doses of liver extract before substitution of folic acid, but most of them had been given large doses of liver extract without improvement in the blood picture. It seems unlikely that the improvement in response to folic acid occurred spontaneously, as a result of a nonspecific effect of folic acid or as a manifestation of the cyclic variations observed in pernicious anemia.⁶

With continuation of folic acid therapy alone there was usually a gradual fall in blood levels and the appearance of slight macrocytosis. This decrease usually became apparent after six to eight months of therapy, but in several cases it did not appear until the twelfth or fourteenth month of therapy. In most cases the blood returned to levels similar to those previously maintained with liver extract alone, but in several patients moderately anemic levels with definite macrocytosis appeared.

These findings may indicate that some factor in addition to folic acid is necessary for maintenance of a completely normal blood picture, and they suggest the possibility that a combination of orally administered folic acid and parenterally injected liver extract may be more effective than either substance alone.

Dosage All patients receiving folic acid in daily oral doses maintained blood levels at least comparable with those previously achieved with liver extract. During the period of our observations a daily oral dose of 1.25 mg of folic acid was as effective as a 15 mg dose in controlling hematologic manifestations. The patients who received the larger doses more frequently showed an initial improvement in

blood levels (table 2), but these higher levels were not better maintained with the larger than with the smaller doses

The injection of folic acid at monthly intervals did not maintain normal blood values. The rate of relapse in a patient who received injections of 30 mg once a month indicated that this amount of folic acid had no effect in maintaining remission. The simplicity and greater effectiveness of orally administered folic acid indicates that the oral route is the rational method of employing the substance.

NEUROLOGIC ASPECTS

Folic acid does not prevent the development or progression of subacute combined degeneration of the spinal cord in patients with pernicious anemia. In this series of 22 patients treated with folic acid, 7 (Cases 1, 8, 10, 14, 15, 17 and 22) developed neurologic relapse, 4 (Cases 3, 4, 12 and 13) showed progression of subacute combined degeneration, and 1 previously untreated case of severe subacute combined degeneration (Case 2) failed to improve during twenty-eight days of folic acid therapy. The blood levels were maintained within the range of normality in all but 1 (Case 1) of the patients who developed neurologic relapse, emphasizing the dissociation of the hematologic and neurologic aspects of the disease, and indicating that the effective hematopoietic factor is distinct from the factor necessary for the maintenance of normal central nervous system function.

Neurologic relapse occurred with considerable suddenness and progressed with great rapidity in several patients. This rapidity of progression was considerably greater than is usually observed in patients with untreated pernicious anemia. Apparently this also was true in similar cases reported by Meyer,⁷ Heinle and Welch⁸ and Vilter et al.⁹

We have continued daily oral administration of 15 mg of folic acid after instituting liver extract treatment in 5 patients (Cases 3, 4, 14, 17 and 22) in whom neurologic relapse developed during folic acid treatment. The period of observation with combined liver extract and folic acid treatment is still quite brief, but there has been progression of neurologic disease in 4 of these cases (Cases 3, 4, 14 and 17). Although improvement in gait and coordination occurred slowly in the fifth patient (Case 22) while folic acid was continued, vibration and position sense did not begin to show improvement until folic acid was omitted two months after the beginning of liver extract treatment.

Development or progression of subacute combined degeneration appeared to occur with the greatest frequency in patients receiving large daily doses of folic acid. Eight patients were receiving 10 or 15 mg daily by mouth when neurologic signs or symptoms first appeared, whereas only 3 developed neurologic disease when the daily dose was 5 mg or less. These observations are not conclusive because 4 of the cases on the 15 mg dosage had previously received smaller doses. These patients might have developed subacute combined degeneration on the lower dosage had it been continued, and the apparent precipitation of neurologic relapse when the dosage was increased may have been coincidental. We are impressed, however, by the fact that of 7 patients (Cases 9, 10, 11, 12, 18, 20 and 21) maintained on a low dosage (5 mg or less a day) for twelve months, only 2 (Cases 10 and 12) showed neurologic relapse. One of these (Case 12) had had long-standing

severe subacute combined degeneration and the progression of his disease was minimal. In marked contrast, of 6 patients treated with 10 or 15 mg of folic acid daily for twelve months (Cases 1, 3, 4, 5, 7 and 8), neurologic relapse occurred in 4 cases (Cases 1, 3, 4 and 8) within twelve months of the last injection of liver extract. The number of cases in each series is too small and the variation from patient to patient in susceptibility to subacute combined degeneration is too great to allow definite conclusions to be drawn from these observations, but it was quite certain that the patients who received large doses of folic acid developed neurologic relapse more frequently than did those who received small doses. It was of interest that of 12 reported cases of neurologic relapse occurring during folic acid therapy all received 10 mg or more of folic acid daily.⁷⁻¹⁰ Heinle and Welch's patient apparently showed acceleration of subacute combined degeneration when the dosage of folic acid was increased to 100 mg daily. The neurologic signs apparently progressed even after liver extract was started, and did not regress until folic acid was discontinued. In contrast to our patients all of the reported cases were in hematologic relapse prior to the induction of folic acid therapy. All but 2 of our patients had been under intensive liver extract therapy before substitution of folic acid. It may be this difference, rather than the larger folic acid dosage, that accounts for the earlier development of subacute combined degeneration in the reported cases. The fact that the majority of our patients did not develop neurologic relapse until twelve months after the last injection of liver extract may have been due to residual stores of liver extract as a result of previous therapy.

The failure of synthetic folic acid to prevent the development or induce the remission of subacute combined degeneration makes it certain that this substance is not the active principle responsible for maintenance of normal nervous system function in pernicious anemia. The possibility that folic acid in large doses actually may exert a deleterious effect on the central nervous system is suggested by three observations: the apparent greater tendency for the development of subacute combined degeneration in patients who received large doses of folic acid, the apparent acceleration of neurologic disease in some patients when folic acid dosage was increased, and the persistence or actual progression of neural disease following institution of liver extract therapy so long as folic acid treatment was continued.

Theoretically it seems possible that synthetic folic acid in large amounts may contribute to dysfunction of the central nervous system by interfering with the metabolism of l (+) glutamic acid by the central nervous system. The observations that suggest this theory are as follows. Quastel and Wheatley¹¹ found that l (+) glutamic acid could be metabolized by nerve tissue, and Krebs¹² showed that brain slices could utilize glutamic acid for the synthesis of glutamine. Weil-Malherbe¹³ demonstrated that l (+) glutamic acid was the only amino acid that could be metabolized by central nervous system tissue. He observed that d (-) glutamic acid actually interfered with brain metabolism. The essential nature of l (+) glutamic acid in nerve function was further emphasized by Nachmansohn et al.,¹⁴ who found that the enzyme system associated with the synthesis of acetylcholine in brain extracts, when inactivated by dialysis, could be reactivated by the addition of l (+) glutamic acid.

These fundamental observations establish the importance of l (+) glutamic acid

in nerve tissue metabolism. They also suggest its possible role in the formation of acetylcholine, a mediator of nervous impulses. Folic acid has the following structural formula

As indicated by the broken line, glutamic acid is one of the constituents of the folic acid molecule, and its position in the molecule suggests that it may be able to enter into competition with l (+) glutamic acid in tissue metabolism and interfere with nerve metabolism, and possibly with the formation of acetylcholine and the transmission of nervous impulses. If this interference does occur, it explains the greater frequency of neurologic relapse in patients receiving large doses of folic acid and the progression of neurologic disease in folic acid treated patients after the institution of liver extract therapy.

That folic acid is connected in some way with acetylcholine metabolism in clinical cases of pernicious anemia is indicated by Davis,¹⁵ who reports that there is a marked *increase* in the serum acetylcholine of patients with untreated pernicious anemia, and that the administration of folic acid, liver extract or ventriculin produces a *decrease* in blood acetylcholine concentration.

We are now investigating the possibility that folic acid may actually contribute to dysfunction of the central nervous system by interfering with l (+) glutamic acid metabolism.

In view of recent reports that l (+) glutamic acid may be effective in the treatment of feeble-mindedness¹⁶ and the possibility that folic acid may interfere with l (+) glutamic acid metabolism, it is of interest that 2 of our patients (Cases 3 and 4) who developed neural relapses were noted by their families to have had mental aberrations.

Whether or not synthetic folic acid in large doses actually interferes with central nervous system function is still to be determined. Clinical evidence proves beyond question that it is not effective in the treatment or prevention of subacute combined degeneration of the spinal cord. For this reason, it is our opinion that no patient with pernicious anemia should be treated with folic acid alone.

SUMMARY AND CONCLUSIONS

I Twenty-one patients with pernicious anemia were maintained on synthetic folic acid (pteroylglutamic acid) therapy alone for periods ranging from eight to

seventeen months Satisfactory blood levels were maintained in all cases receiving daily oral doses of 1.25 to 15.0 mg Severe hematologic relapse occurred within six months in a case treated with monthly injections of 30 mg

2 Synthetic folic acid in oral doses of 15 mg daily induced satisfactory hematopoietic responses in 3 patients with pernicious anemia in severe relapse, but only slight hematopoietic response in a fourth patient with mild pernicious anemia but severe subacute combined degeneration of the spinal cord

3 Ten patients showed a significant improvement in blood values for a few months after substitution of folic acid for liver extract With one exception these subsided after six or more months to pre-folic acid levels comparable with those previously maintained with liver extract alone

4 These observations suggest that a combination of orally administered folic acid and parenterally injected liver extract may maintain a better hematologic status than either substance alone

5 A previously untreated patient with severe subacute combined degeneration of the spinal cord failed to show improvement in neural disease during twenty-eight days of folic acid therapy

6 Eleven patients developed, or showed progression of, subacute combined degeneration of the spinal cord during folic acid treatment Neurologic disease developed in most of these patients when the peripheral blood was normal

7 One patient showed an extremely explosive onset and rapid progression of neural disease The progression of the disease was rapid in 3 other cases

8 The institution of liver extract therapy in addition to folic acid in 5 patients who developed subacute combined degeneration during folic acid maintenance therapy failed to prevent progression of the disease in 4 cases, and only partially arrested the disease in the fifth, in which improvement occurred more rapidly when folic acid was discontinued

9 Subacute combined degeneration occurred with greater frequency in patients on large daily doses of folic acid than it did in patients with small or intermittent doses

10 The possibility is discussed that folic acid in large daily doses may actually precipitate or aggravate neurologic disease

11 It is suggested that folic acid may interfere with the metabolism of l(+)-glutamic acid in the central nervous system and possibly disturb the formation or function of acetylcholine

PERNICIOUS ANEMIA CAUSED BY DIPHYLLOBOTHRIUM LATUM, IN THE LIGHT OF RECENT INVESTIGATIONS

By BERTEL VON BONSDORFF, M D

THE MACROCYTIC anemia caused by the broad fish tapeworm, *Diphyllobothrium latum*, has been the subject of extensive investigations in Finland, starting with the pioneer work of J W Runeberg (1887) and O Schauman (1894)

The fish tapeworm is extraordinarily common in the country. In certain provinces more than 90 per cent of the population is infested with the parasite. Of the total population of the country, which is about 4,000,000, one half to one million can be considered to be tapeworm carriers. The parasite is found in persons of all ages, even in children under 1 year of age.

For most of these carriers, the worm is a relatively innocent parasite, but in some, it causes a macrocytic anemia. According to earlier investigations (R Ehrstrom, 1926) the frequency of anemia was estimated to be 1 case in 5,000-10,000 worm carriers. But, if the blood of worm carriers is examined systematically, a far greater number of anemia cases can be shown. Among the conscripts of 20 years of age admitted to a military hospital in peace time, Seppa (1927) found 1 case of anemia in 659 worm carriers. G Totterman (1944), in a community strongly infested with tapeworm, noted, in 1942, 1 case of anemia in 136 carriers, and in 1943, he found the frequency to be 1 case of anemia in 383 carriers. In a war hospital, from 1941 to 1944, I found 96 instances of tapeworm anemia in about 11,000 medical cases. The number of worm carriers in this group, composed of men from 18 to 40 years of age, is not known.

The above figures give a good idea of the importance of the problem of tapeworm anemia in Finland. This anemia is a typical "pernicious anemia" with a characteristic blood picture and a megaloblastic bone marrow, agreeing in all respects with that found in "cryptogenetic" Addisonian anemia. A pernicious tapeworm anemia can also be brought to remission with liver preparations per os or parenterally, or with stomach preparations per os without removal of the worm.

In contrast to cryptogenetic pernicious anemia, tapeworm anemia occurs even in people under 20 years of age. In most cases there is an achlorhydria after the injection of histamine, though, especially in younger patients, the gastric juice often contains free hydrochloric acid and is secreted in the usual quantities. Signs of spinal cord involvement are less apparent than in cryptogenetic pernicious anemia.

That the illness is really due to the worm infestation is proved by the fact that complete remission takes place after the worm is expelled without any further need for antianemic treatment.

Since cryptogenetic pernicious anemia is not rare in Finland and worm infestation is common, it is natural that now and then both types of anemia should occur simultaneously in an individual. In such cases, of course, there is no remission after the worm cure. In fact, the anemia often becomes more severe.

From the University of Helsingfors, Finland

G Totterman (1944) says that he has encountered cases of mild macrocytic anemia in tapeworm carriers that did not respond to liver treatment but showed good remission after a worm cure. He assumes that the pathogenetic mechanism for this form of anemia is different from that for the true pernicious tapeworm anemia, which does respond to liver therapy.

On the other hand, there have been numerous reports in Finland of cases of hypochromic anemia in tapeworm carriers which were not cured by expelling the worm. On this point, conflicting information is still found in the literature.

The question which is of special interest for research is why do so few worm carriers have pernicious anemia? Or formulated in greater detail what are the factors which lead to the rise of worm anemia and why are these factors active in only a small number of cases?

Hitherto, these questions have not been satisfactorily answered. The discussion of them and the tapeworm anemia problem as a whole has been reported in detail by Birkeland (1932).

The present knowledge of the genesis of pernicious anemia suggests that in some way the worm interfered with the production or absorption of the antianemic factor or with the production of the components involved in its formation. This thought was first expressed by Saltzman (1935). On the basis of similar reasoning the pernicious anemia in connection with sprue, ventricular lesions, intestinal resections, etc., can, as is well known, be explained.

An investigation is here reported carried out on these lines with the object of explaining the pathogenesis of cases of pernicious anemia, most of them due to tapeworm infestation. The tests have been going on since 1937.

1 THE INTRINSIC FACTOR

a) *The course of remission after removal of the worm.* If the worm is expelled in the usual way (with 3-4.5 Gm. *Extractum filicis*) from hospital patients on an unrestricted diet, a blood remission begins shortly afterwards and continues until the blood picture has become normal. In a group of 7 cases, it was observed that the reticulocytosis began on the fourth to the sixth day after the worm was expelled in 6 of the patients and in 1 case, not until the eleventh day. The reticulocyte maximum was reached in the first 6 cases mentioned between the seventh and the tenth day after the worm cure, and in the seventh case on the thirteenth day. The maximum reticulocyte values varied between 7.4 and 23 per cent. In these cases, examination of the blood before *Extractum filicis* was given showed that the erythrocytes were between 1.2 and 2.1 million per cu. mm. of blood.

Apparently, after the worm cure, the reticulocytosis generally sets in a few days later than after a strong initial liver treatment. The maximum for reticulocyte values is on the average somewhat lower than in cases of pernicious anemia treated with liver, but on the other hand, the reticulocyte crisis lasts longer. The increase of the erythrocytes is generally about 100,000 per day, which is just as great as with adequate liver therapy.

It has been found by means of a sternal puncture that within 48 hours after the

worm cure, the megaloblastosis in the bone marrow gives way to a normoblastic type of regeneration

The most rational therapy in pernicious tapeworm anemia is the simple worm cure. Only in very severe anemia is it necessary to start treatment with liver injections and not expel the worm until after the blood picture has improved. In such cases, however, it is difficult to decide afterwards whether the pernicious anemia was caused by the worm or not. Only if the patient is very young and/or has free hydrochloric acid in the gastric contents can one be to some extent certain that the pernicious anemia was caused by the tapeworm.

The fact that the pernicious tapeworm anemia is completely cured after the worm is expelled can be explained in no other way than that the patients have access to all the substances required for the endogenous formation of the antianemic principle. Evidently, these substances are available directly after elimination of the worm, as indicated by the promptness with which the remission begins thereafter. If the food contains the extrinsic factor, this must imply above all that the intrinsic factor becomes at once available.

b) *Castle's test with gastric juice from patients with pernicious tapeworm anemia* Hernberg (1936-1941) has shown that the gastric juice in patients with pernicious tapeworm anemia, as well as in persons who have had it, contains intrinsic factor. Mixed with meat, such gastric juices produce a typical remission when given to patients with cryptogenetic pernicious anemia.

c) *In vitro experiments* The author has made some investigations of the proteolytic gastric enzyme active at neutral reaction according to the method given by Taylor et al. (1938), and has found (1940) that this enzyme occurs in pernicious tapeworm anemia as well as in cryptogenetic pernicious anemia, though in the latter cases the total amount of the gastric secretion is very much reduced. It has been suggested that this enzyme is identical with the intrinsic factor. My results have been confirmed by Helander (1945). Hernberg (1939) with Lasch's reaction has obtained similar results in the gastric juice from patients with pernicious tapeworm anemia.

The investigations here reported, all support the idea that the gastric juice of patients with pernicious tapeworm anemia contains intrinsic factor. In spite of this, and in spite of the fact that the amount of gastric juice is often normal, an anemia has arisen. Apparently the pernicious anemia in tapeworm carriers is not caused by cessation of the secretion of the intrinsic factor because of the presence of the worm. However, it is evident that some inhibition of the gastric juice secretion may occur in connection with pernicious tapeworm anemia, for in some cases free hydrochloric acid reappears in the gastric contents after the remission in patients who showed achlorhydria while the anemia was apparent.

The author has been unable to find any difference in the speed of remission after a worm cure in patients with achlorhydria and those with normal gastric secretion.

It seems possible that a decreased secretion of intrinsic factor may facilitate the occurrence of a pernicious anemia in connection with tapeworm infestation. It is well known that some people who have had a pernicious tapeworm anemia when young, have later fallen ill with a cryptogenetic form of the disease. In some

families many cases occur of both cryptogenetic anemia and pernicious anemia due to worm. The cause of this has been considered a special constitutional disposition for this type of anemia. It may be that this "disposition" consists in a deficient production of intrinsic factor.

2. THE EXTRINSIC FACTOR

a) *Clinical observations* Experience in Finland shows that worm carriers can have pernicious anemia even though their food contains a sufficient amount of protein of different kinds. Apparently, lack of extrinsic factor is not essential for the occurrence of pernicious tapeworm anemia (in contrast to some other conditions such as, for example, the nutritional tropical pernicious anemia). However, certain facts do support the idea that a relative deficiency in extrinsic factor can contribute to the rise of the disease. G. Totterman found in his material a higher frequency of pernicious tapeworm anemia in 1942 than in 1943. In the former year the food situation in our country was particularly serious, there was a special lack of proteins. The next year the situation had improved considerably. My own experience agrees with that of Totterman's. In some cases of worm anemia, I have seen a slight reticulocytosis and even a certain improvement of the erythrocyte count during the administration of meat. This was the case with soldiers who came for treatment directly from the front. Cramer (1922) observed pernicious tapeworm anemia at the same time in 3 sisters who, by reason of some mental peculiarity, lived like hermits and fed themselves with an extremely insufficient diet.

b) *The course of remission after removal of the worm in the absence of extrinsic factor* It is logical to assume that there will be no remission after the worm is expelled if the patient, shortly before and after the worm cure, has taken food containing no extrinsic factor. The correctness of this reasoning has been shown in a series of twelve tests. When the patients were admitted to the hospital they were placed on a basic diet as free from extrinsic factor as possible. After some days, they were given a worm cure. Very insignificant signs of blood regeneration, or none at all, were observed even after twelve to fifteen days. On the contrary, the blood picture often became progressively more abnormal. As soon as substances known or believed to contain extrinsic factor were added to the diet, a marked reticulocytosis began and the blood picture improved rapidly. It has been proved that this is true when meat, milk, Hammarsten's casein, pepton, brewer's yeast and concentrated yeast extract and, to a lesser degree, soy bean protein were added to the diet. These observations confirm Castle's theory that both intrinsic and extrinsic factor are necessary.

The method furnishes a means of testing substances for their content of extrinsic factor.

One practical conclusion is that, after worm cure, patients with worm anemia must be given a diet rich in proteins if a rapid remission is to be expected.

3. THE INTERACTION BETWEEN THE INTRINSIC AND EXTRINSIC FACTORS

Castle's test has not been previously carried out on patients with pernicious tapeworm anemia, yet this experiment is of great importance. It is conceivable that

the worm in the intestinal canal prevents the interaction between extrinsic and intrinsic factors and in this way gives rise to the pernicious anemia. If this is true, it would be expected that no remission would occur when a patient is given a mixture of meat and gastric juice. This would indicate that the worm has been able to destroy the effect of these substances supplied from outside in the same way as it prevents the body's own intrinsic factor from interacting with extrinsic factor in the patient's ordinary food. If a fresh mixture of gastric juice and meat proves to be ineffective while the same mixture incubated for six hours at 37°C does have an antianemic effect, the conclusion might be drawn that by means of the enzyme activity *in vitro*, some new substance is formed which the worm is unable to injure.

A series of 14 tests was carried out to clear up this question. Meat (150 Gm per day), or in some tests yeast extract, was used as the source of the extrinsic factor. The daily amount of gastric juice with which the meat or yeast was mixed was 150–175 ml. Each test period lasted eight days. During the first test period a nonincubated mixture was given.

In some cases of cryptogenetic pernicious anemia these tests produced a splendid remission. The effect was equally good whether the mixture was incubated previously or not. On the other hand, the test results were clearly negative in cases of pernicious tapeworm anemia. Neither fresh nor incubated mixtures of meat and gastric juice produced any remission. In some cases the identical gastric juice was used as in parallel tests with cryptogenetic pernicious anemia. The remission occurred only after the worm had been expelled.

In one case of pernicious tapeworm anemia, 100 ml of gastric juice was brought up daily after insulin stimulation, and was incubated with 150 Gm of meat for six hours, after which the mixture was administered to the patient. Not even in this way could any remission be produced.

These observations give strong support to the idea that the worm in the intestinal canal is capable of preventing interaction between the extrinsic and intrinsic factors and that such an inhibition can be deemed to be the reason for the pernicious anemia.

The fact that incubation does not involve an improvement of the antianemia effect of meat and gastric juice confirms the assumption that the antianemic principle cannot be formed *in vitro* but only *in vivo*. It is possible that the interaction between extrinsic and intrinsic factors takes place in the intestinal wall (Formix-nex, 1940). Perhaps this interaction is not a simple enzyme reaction.

4 THE LIVER FACTOR

If the worm in pernicious tapeworm anemia is expelled and the formation of new antianemic factor is prevented by giving a diet free from extrinsic factor, then, as already stated, there is no blood remission. This shows that the liver must be deprived of its stock of antianemic factor, for if any were present, blood regeneration should take place after the anemia-producing worm had been removed, independently of the supply of intrinsic and extrinsic factors.

It is conceivable that the worm may destroy the antianemic factor at the place where it is assumed to be formed, *i.e.* in the intestine. Another possibility is that

the worm toxins absorbed from the intestine may destroy the entire quantity of antianemic liver factor available in the body, but this is an improbable theory

It is a priori somewhat improbable that the tapeworm can injure the liver factor, partly because it is rather stable and partly because we know that the administration of liver preparations both parenterally and per os quickly cures a pernicious tapeworm anemia

I have incubated ordinary injectable liver extracts together with worm in vitro at 37° C for some days and could not, at least in this way, prove any decrease of their antianemic effect

It appears, then, that the lack of the liver factor is not the result of destruction by the tapeworm itself nor by toxins from the worm

5 FOLIC ACID

I have treated 4 cases of pernicious tapeworm anemia with folic acid per os. An excellent remission was obtained in all cases with doses of 20-30 mg daily for 7-10 days, showing that folic acid also is not injured by the worm

6 THE ABSORPTION

The clinical picture in pernicious tapeworm anemia gives no reason to believe that the absorption in this disease is impaired. Carriers of *Diphyllobothrium latum* seldom suffer from severe intestinal disturbances. Worm carriers with and without anemia do not differ from each other in this respect. In no case are the conditions comparable with those in sprue, intestinal anastomoses, etc.

The glucose tolerance test has been carried out in 4 cases of pernicious tapeworm anemia, both before the worm cure and after the blood had become normal. In all cases the blood sugar curve had a normal course both before and after the worm cure, thus it was not possible to show that there was any disturbance in the glucose absorption.

7 EXPERIMENTAL FEEDING WITH TAPEWORM PREPARATION

The effect on the blood of giving worm preparations per os or parenterally has, of course, been studied in both animals and humans. T. W. Tallqvist (1907) experimented on himself in this way and G. Totterman (1938-1940) has published a large series of tests. Both have thought they saw a certain anemizing effect from the preparations they used. I am not convinced of the correctness of their conclusions for reasons stated in another publication.

The problem has been attacked by attempting to answer the following questions: (1) Is the antianemic effect of the mixture of gastric juice and meat nullified if worm is added? (2) Is the remission after the worm cure absent in worm anemia patients if the worm preparation is given per os?

The mixtures of gastric juice and meat (or yeast extract) were prepared in the same way as described earlier. The subjects were patients with untreated cryptogenetic pernicious anemia. First they were treated for eight days with gastric juice plus meat (or yeast extract) with the addition of a considerable amount of fresh or dried *Diphyllobothrium latum*. The remission was always splendid. During the

following period with gastric juice plus meat (or yeast extract) without the addition of worm, no new reticulocytosis was observed and the blood regeneration was no more rapid than during the first test period

In one case of worm anemia the patient, after the worm cure, was given worm powder per os in increasing amounts. In spite of this the blood improved in the usual way

In some tests the worm anemia patients were kept on a diet free from extrinsic factor, were given worm cure and then for eight days extrinsic factor in the form of yeast extract with the addition of worm powder. In spite of this addition the blood improved rapidly

In connection with these tests, worm powder was mixed with hog's stomach in order to investigate the possibility of loss of antianemic effect. In spite of the addition of powdered worms in two such tests the hog's stomach still had a marked antianemic effect

It was thus shown that addition of worm is unable to destroy the antianemic effect of mixtures of gastric juice and extrinsic factor, or of stomach preparations. Moreover, the presence of worm does not prevent the remission after the elimination of the worm in worm anemia. This fact has been interpreted to mean that the inhibition of the interaction between the intrinsic and extrinsic factors can be produced only by the living worm in its natural surroundings at the place where the interaction occurs

8 INHIBITION IN VITRO OF THE PROTEOLYTIC ACTIVITY OF GASTRIC JUICE AT NEUTRAL REACTION

The gastric protease which is active at a pH range from 5 to 9 is greatly inhibited in its hydrolytic capacity in vitro after the addition of even relatively small amounts of *Diphylobothrium latum*. The inhibitory substance is destroyed by heating to 80° C. for twenty minutes. It is not dialyzable and is not soluble in ether, nor in 98 per cent ethyl alcohol. It cannot be precipitated with 50 per cent alcohol, but can be precipitated quantitatively in 90 per cent alcohol.

The gastric protease in question has been assumed to be identical with the intrinsic factor, and the hydrolysis of casein in vitro has been considered as corresponding to the interaction between the intrinsic and extrinsic factors in vivo. It has not yet been possible to prove this assumption. As stated above it seems probable that such interaction cannot occur in vitro but only in the intestinal canal.

There is thus a discrepancy as follows: (a) The living worm in situ seems to inhibit the interaction between the extrinsic and intrinsic factors, (b) the administration per os of worm preparations does not inhibit this interaction, while again (c) the addition of worm in vitro inhibits the proteolytic activity of gastric juice at neutral reaction. It seems that this discrepancy cannot be explained until we have more detailed knowledge of the different substances here concerned. The exact chemical nature of the extrinsic factor, intrinsic factor and the tapeworm toxin are as yet unknown.

9 THE LOCALIZATION OF THE TAPEWORM IN THE INTESTINAL CANAL

Presumably the worm cannot inhibit the reaction between extrinsic and intrinsic factor unless the worm is present at the place where the interaction occurs. Now the question arises: Where in the intestinal canal is the worm to be found? Very uncertain information on this point is available. Experience from operations and autopsy in general indicate that the worm has been chiefly observed in the ileum, but there are no systematic observations of this fact. Sometimes it happens that *Diphyllobothrium latum* is vomited, which shows that at least occasionally it can be very high up in the intestine. To investigate this question, the author made a series of intestinal intubations. As the *Diphyllobothrium latum* produces large quantities of eggs it was relatively easy to determine at what distance from the

TABLE 1 — Distance from Mouth (cm.) where Ova and/or Proglottids of *Diphyllobothrium Latum* Were Found

Group 1 No anemia	Group 2 Nonpernicious anemia	Group 3 Pernicious tapeworm anemia, manifest	Group 4 Pernicious tapeworm anemia in spontaneous remission
235	334	135	320
235	180	120	240
230	140	120	205
180		120	
180		115	
180		115	
165		110	
150		105	
145		105	
130		95	

mouth the first eggs could be aspirated. In many cases small pieces of the worm itself were aspirated at the same time. Of course, it is not possible to calculate in this way the highest point in the intestine where the worm is attached. Although no eggs are produced from the highest segments of the worm, yet I have been convinced that results can be obtained which allow comparison between different cases.

The intubations were carried out on 26 worm carriers who were divided into 4 groups as appears in table 1, in which the results are also summarized.

The results show that in manifest pernicious anemia the worm is found higher up in the intestine than otherwise. Perhaps one can imagine that in that region it is better able to interfere with the interaction between extrinsic and intrinsic factors. How high up in the intestine the worm must be for it to inhibit this reaction is difficult to determine. My results favor the opinion that a 'critical limit' lies 140-150 cm. from the mouth, which ought to be about the borderline between the jejunum and the ileum.

10 AN ATTEMPT TO EXPLAIN THE PATHOGENESIS OF THE PERNICIOUS TAPEWORM ANEMIA

As described above, it appears to be possible that the *Diphyllobothrium latum* causes pernicious anemia by inhibiting the interaction between extrinsic and intrinsic

sic factors, but that this reaction can occur only if the worm is sufficiently high in the intestine. However, as stated previously, there is reason to presume that the amount of extrinsic factor in the food and of intrinsic factor in the gastrointestinal canal is also of some importance. Thus whether anemia occurs or not would depend on a definite correlation among these three determinants: the amount of extrinsic factor, the amount of intrinsic factor, and the worm's high or low position in the intestine.

Finally a time factor must also be taken into consideration. The formation of antianemic factor must have been inhibited for such a long time that the liver is wholly deprived of it. Only then is there reason to expect that the anemia will manifest itself.

It must be emphasized that in the great majority of cases of pernicious tapeworm anemia, there is no basis for the assumption that either a defective diet or a hereditary disposition are to be reckoned with as co-operating causes. Most tapeworm anemia patients do *not* fall ill later with a cryptogenetic anemia. I can, therefore, not confirm the correctness of Birkeland's conclusion that "it seems appropriate to classify surviving patients with *Diphyllobothrium* anemia as suffering from abortive forms of genuine pernicious anemia." My view of the problem is that in principle any worm carrier whosoever can get a pernicious tapeworm anemia if only the worm—*ceteris paribus*—is high enough up in the intestine. If the worm is expelled a complete restitution can follow.

The theory I have formulated explains—in my opinion—the following circumstances which have been specially put forward by Saltzman (1924) and which have hitherto been difficult to interpret:

a) *A person can carry *Diphyllobothrium latum* for many years before he falls ill with pernicious anemia.* The explanation of this can be that the worm, for one reason or another, has invaded the upper parts of the intestine, sometimes possibly as a reinfection.

b) *A person who has had pernicious worm anemia and becomes well after the worm is expelled does not necessarily get anemia if he is again infested with worm.* At the reinfection it may happen that the worm is only in the lowest parts of the intestine.

c) *A worm expelled from an anemia patient is often disintegrating and discolored.* Sometimes no worm at all is seen in the feces. According to my theory, this disintegration can be due to the fact that the worm, being higher up in the intestine, has had a longer distance to go before it was expelled. During its passage through the intestine it has had to undergo a strong autolytic decomposition and is also affected more by the digestive enzymes than if it had been in the lower part of the small intestine and only had to pass through the colon, where the enzymes are less active.

d) *The amount of worm is not in correlation with the occurrence of anemia.* A small amount of worm can cause anemia if it is sufficiently high up in the intestine, while a large amount does not necessarily do so if it is collected in the lower part of the small intestine. Yet cases with very large amounts of worm, 80–100 M and more, are often accompanied by anemia. In such cases it can be imagined that the worm, because of its great volume, has been forced upwards towards the jejunum.

e) *Spontaneous remission* with a return to normal blood values are not rare in worm

anemia The explanation of this can be that the worm had deserted the upper parts of the small intestine and wandered down towards the ileum In my 3 cases of this type the worm was found just as low in the intestine as in nonanemic worm carriers (cf table 1)

f) *Remission after an incomplete worm cure can also occur* A filicin cure can fail in such a way that only a small amount of the worm, or none at all is expelled, and after the cure worm eggs can still be seen in the feces In spite of this, the blood improves At a later worm cure—after the blood picture has become normal—a considerable amount of worm is often removed In such cases—according to my idea—the worm at the first 'unsuccessful' cure was driven from the upper part of the intestine but remained in the lower part where it was no longer able to exercise its anemia-producing effect

This idea was confirmed by the following test In one case of manifest pernicious worm anemia the eggs were found 115 cm from the mouth Through the intestinal tube 2 Gm filicin emulsion were instilled The worm was not expelled and the feces continued to contain worm egg, but they could not be demonstrated as present at the former depth (115 cm) A few days after the filicin cure a marked reticulocytosis began and the blood picture improved rapidly The tube was then allowed to glide farther in, and worm eggs were not found till 200 cm from the mouth, that is, far down in the ileum Following another treatment with filicin, 31 M of ordinary looking *Diphyllobothrium latum* were expelled

COMMENT

According to one earlier theory, the occurrence of worm anemia may be due to a change in the character of the parasite, possibly an abnormal disintegration of the worm in the intestine, but I have been unable to find any signs of such a disintegration The worm segments which I sometimes aspirated at intubation from worm anemia patients have been very motile and of ordinary appearance According to other theories, the cause of the anemia lay in the host These theories have presumed a varying permeability of the intestinal wall to the worm toxin, a special, individual susceptibility of the hemopoietic organs to it, or an allergic preparedness, G Törterman has classed the pernicious tapeworm anemia with the malignant granulocytopenia due to the use of amidopyrine Apart from the fact that I find the experimental basis of these theories defective, none of them seem to me to explain the worm anemia problem satisfactorily It appears artificial to conceive of the macrocytic anemia with its megaloblastosis as an allergic reaction Another fact that tells against the toxic and allerge-toxic theories is that the anemia can be cured with liver or stomach preparations without expulsion of the worm Again, on the basis of them, it is difficult to explain why no remission occurs after the worm cure unless extrinsic factor is available The circumstances listed under Section 10 (a-f) above are also not easy to explain

There is no doubt that *Diphyllobothrium latum* contains a powerful poison If one handles fresh worm with unprotected hands, the skin is greatly irritated If one places a small amount of dried and pulverized worm on the tongue, there is a feeling of burning The inhalation of worm powder has been proved to produce nausea,

fever, rhinitis, asthmatic cough and eosinophilia in the blood. A worm carrier often suffers from giddiness, various nervous manifestations and nausea, has eosinophilia (which may or may not be absent in anemia cases) and shows serological changes. Like the macrocytic, nonpernicious anemia described by G. Totterman, these phenomena can be considered as the expression of the effects of toxic activity, resembling those which condition the rise of pernicious anemia. Thus, according to my idea, the inhibition of the interaction between extrinsic and intrinsic factors is only *one* expression of the worm's toxicity.

Tests on animals with worm preparation injections also bear witness to the toxicity of the worm. Among other things, it appears to contain a hemolytic toxin. Yet it has not been possible with these tests to produce an anemia which directly corresponds to the Addisonian anemia in man.

Much confusion in the discussions could, I believe, be avoided if the ability of the worm to produce pernicious anemia was consistently kept separate from its other toxic properties.

Certain details in the tapeworm anemia problem still await solution. Like the cryptogenetic pernicious anemia, the pernicious tapeworm anemia shows definite variations in its seasonal distribution. It is most usual during the period from March to August. Illustrative curves with which my own experience agrees are to be found in Birkeland's monograph. It is at present impossible to decide to what extent these seasonal variations depend on circumstances in the patient himself on light conditions, on the contents in the diet of protein, folic acid (as suggested by Waldenstrom), or other substances. A racial factor (in connection with pigment metabolism) must also be taken into consideration in both forms of pernicious anemia.

The chemical nature of the worm's toxin is still unknown. If that could be determined, it might be possible to get a better idea of the process by which the poison interferes with the interaction between the extrinsic and the intrinsic factors.

I have tried to show here that the investigation of pernicious worm anemia has not only a local interest but can also contribute to the elucidation of the whole great question of the macrocytic and megaloblastic anemias which respond to liver treatment and which are termed "pernicious."

THE STUDY OF THE MYELOGRAM (BONE MARROW PUNCTURE) IN PERNICIOUS ANEMIA AND THE PROBLEM OF THE MEGALOBLAST

By JACQUES MALLARMÉ, M D

OF ALL the recent advances in medicine, the conquest of pernicious anemia is one that should make pathologists proud. Twenty-five years ago, Biermer's anemia was a pernicious anemia, often fatal and which could not be cured by any treatment. It is fair to acknowledge the brilliant work of Minot and Murphy, who conceived the idea of applying the liver treatment inaugurated by Whipple, to pernicious anemia. The results were such that since then, patients with pernicious anemia do not die of the disease any more. Simultaneously, hepatotherapy has provided a convincing argument in favor of the specificity of the disease. Confusion with other severe types of anemia has been avoided. In addition to hepatotherapy other arguments have supported the concept of pernicious anemia as an autonomous disease, entirely distinct from other types of anemia. Among these arguments, one of the most recent is based on the study of the myelogram in pernicious anemia.

The cytology of the bone marrow was already known before the use of sternal punctures. However, postmortem examinations are vitiated by the onset of cadaveric changes in the tissues. Therefore, the sternal biopsy is indispensable to an understanding of the bone marrow. This is why the technic of bone marrow biopsy, introduced in 1929 by Arinkin, provided a great impetus to the development of hematology. This applies particularly to the study of pernicious anemia.

Sternal puncture is a simple procedure carried out with a special needle containing a stilet, which penetrates easily through the anterior table of the sternum, local anesthesia is not necessary. The bone marrow is aspirated in very small quantities if one wants to have a rich myelogram. Reading of the myelogram is easy if the technic of preparation is adequate: spreading—compression between two slides of a very small quantity of tissue, preferably small fragments of bone marrow—double staining by May-Grunwald-Giemsa for one-half hour. The water used should have a neutral pH.

Naegeli first described the erythroblasts which characterize pernicious anemia. He called them *megaloblasts* and this term was responsible for much of the confusion that prevailed thereafter. This confusion arose from the fact that Ehrlich and also Jolly gave the name 'megaloblast' to certain types of very young erythroblasts which are basophilic and are found in any normal marrow. These are not the megaloblasts which are found in pernicious anemia. These normal erythroblasts are also called pronormoblasts, basophil normoblasts or Naegeli's normoblasts.

The megaloblasts found in pernicious anemia represent a special lineage of erythroblasts, ultimately ending up in a special type of erythrocyte, the megalocytes, and having a characteristic morphology at each stage of the cytologic development.

As seen in the bone marrow smear, the megaloblasts of pernicious anemia have a high optical density. The youngest forms arising from the reticulum are the promegaloblasts (called "erythrogonos" by certain authors). They have a histioblastic appearance with a grayish blue protoplasm, more or less spread out, not sharply limited, with pseudopods and sometimes a protoplasmic connection with another promegaloblast. The nucleus is enormous and the chromatin shows a fine lacy structure with numerous bluish nucleoli.

Following the promegaloblasts come the basophilic megaloblasts which are frequently seen. These cells are large with a big round nucleus centrally placed. The chromatin has a fine skeinlike structure and is transparent. The protoplasm is very basophilic, has a variable thickness and is usually quite wide. In some cases, the basophilic megaloblast shows early eosinophilic granules.

As maturation progresses, the cellular anarchy becomes more manifest and the aspect of the megaloblast diverges more and more from that of the normoblast. The nucleus remains large, with a fine transparent chromatin, which in places condenses into pearl-like or blocklike structure. The peripheral protoplasm becomes lighter in an irregular fashion and its maturation may lag behind or, more often, precede that of the nucleus.

The fourth stage of the development is that of polychromatophilic megaloblast. The asynchronism between nucleus and protoplasm becomes manifest. A big nucleus may be found in conjunction with a small cytoplasm or a small nucleus in conjunction with a large cytoplasm. The cytoplasm shows vivid colors, purple or greenish with heterogeneous areas of variable shapes. The nucleus still has a partly reticulated structure and may undergo amitotic division or fragmentation which produces an aspect of a petalled flower. The nucleus is still young as shown by its transparent and pearl-like aspect. But the tendency toward the formation of fragments of the nucleus classifies the cell as an old type of cell. The nuclear fragments appearing early in the cell are the future Jolly's bodies.

The orthochromic megaloblasts have an orange color but may contain basophilic remnants in the form of basophilic areas or granules as in lead poisoning. The nucleus may be round and regular as the nucleus of the orthochromic normoblast, but more often it is reniform or dumbbell-shaped or has the shape of a clover leaf. The orthochromic megaloblasts vary in size and some may be rather small. When they lose their nucleus they become remnants, Cabot's rings, and Jolly's bodies. The megaloblasts in pernicious anemia often show atypical mitotic figures at all phases.

In summary, at all stages of the evolution, the megaloblast is an abnormal dystrophic erythroblast resulting in the creation of a large erythrocyte. This explains the anisocytosis, poikilocytosis and megalocytosis which are the expression of a cellular dystrophy and not of a cellular immaturity since most cells observed in the blood smear of a case of pernicious anemia are completely mature cells.

After a long period of discussion, hematologists agree among themselves that the megaloblastosis belongs specifically to pernicious anemia. I, personally, do not think that megaloblasts are observed in any anemia except pernicious anemia, provided one adheres to the definition of the megaloblast as I have given it, and one does not consider the megaloblast as a very young nucleated basophilic erythrocyte.

Every time I have been invited to see so called megaloblasts in the myelograms from patients having blood disease but no pernicious anemia, I have recognized that these were not megaloblasts. While the megaloblast is specific for pernicious anemia, there are also normoblasts and their proportion to the number of megaloblasts is variable. They are seen in early cases of pernicious anemia. Also they completely and rapidly replace the megaloblasts as soon as hepatotherapy is instituted. This fact permits one to conclude that the megaloblastosis is conditioned by a deficiency of the hemopoietic factor of maturation of red cells which is provided by the liver.

The generally accepted opinion, proposed by Naegeli, by Ferrata, and most hematologists is that the megaloblast represents a revival of the embryonic erythrocyte of the first generation. There is a certain morphologic analogy between the megaloblast and the nucleated erythrocyte of the fetus. One arrives therefore at the conception, as already advanced by Dameshek and Wilkinson and Israels, that there are two types of hemopoiesis: the normoblastic or adult type and the megaloblastic or embryonic type. Their appearance or disappearance depends on the factor of Whipple: if the maturation factor is deficient, the fetal type of erythroblasts appears in the bone marrow but if the factor is administered, the normal type of erythroblasts replaces the megaloblasts.

My interpretation is a little different from what precedes. The megaloblast does not appear as the result of a substitution of two erythroblastic lineages, because such a substitution is never observed. Rather than a substitution, a real transformation occurs which changes the normal erythroblast into a megaloblast: this morphologic transformation is caused by a deficiency of the maturation factor. In other words the megaloblast is a normoblast suffering from a nutritional deficiency.

This interpretation explains several particularities of the disease: first of all, the megaloblast may exhibit morphologic monstrosities in a varying degree according to the degree of the deficiency. This is analogous to what is seen in dystrophies caused by endocrine or vitamin deficiencies. In very advanced cases of pernicious anemia, the megaloblasts are typical and numerous. In incipient cases, the erythroblasts are not very much different from normoblasts and there are intermediary forms between normoblasts and megaloblasts. Finally when the treatment by liver injections is instituted, there is a rapid transformation of the megaloblasts into normoblasts.

The metaplasia from normoblast to megaloblast, or vice versa, always affects the young forms of the series: proerythroblasts and basophilic erythroblasts. This is why in cases of pernicious anemia in relapse the young basophilic cells are megaloblastic while the older cells are normoblastic. As soon as the liver treatment is instituted, the myelogram shows a normoblastic transformation of the basophilic erythroblasts without change in the polychromatophilic and orthochromic megaloblasts.

Another proof of the existence of a nutritional dystrophy in pernicious anemia is provided by the aspect of the granulocytes and megakaryocytes of the bone marrow.

The granulocytes show morphologic changes: the myelocytes are very large and

pale looking with enormous nuclei. The metamyelocytes have a ribbon-shaped nucleus with pseudopods. The polymorphonuclears have a polysegmented nucleus (up to 15 segments) giving the appearance of a knotted chord.

The megakaryocytes also have a polysegmented nucleus. All the cells formed in the bone marrow are affected in pernicious anemia. *Biermer's disease is a dystrophic myelosis, affecting the bone marrow as a whole, and producing anemia, neutropenia and thrombocytopenia.* The morphologic changes resulting from the dystrophy are specific and constitute the basis for the diagnosis.

From a scientific point of view, the myelogram in pernicious anemia is very interesting because it constitutes an instance of a cytologic dystrophy which can be reversed by the administration of liver, of Castle's factor, of folic acid.

One cannot help being struck by the analogy between the cytologic dystrophy of pernicious anemia and certain cellular alterations of malignant neoplastic tissues. In both cases there is the same excessive proliferation, the same cellular monstrosity, the same cytoplasmic-nuclear asynchronism, the same young aspect of the nucleus, same abnormal mitotic or amitotic cellular division.

On the other hand, hepatotherapy or folic acid treatment are very similar to vitamin therapy.

At the present time, therefore, one can say without exaggerating too much that pernicious anemia is a nutritional deficiency and a disease rather akin to cancer, in which the abnormal cellular proliferation is corrected by a chemically defined organic substance.

REFRACTORY MEGALOBLASTIC ANEMIA

By L S P DAVIDSON, B A , M D , F R C P Ed AND LOND , F R S Ed

THE TERM "refractory anemia" was introduced by Bomford and Rhoads (1941) for anemias of a wide variety of types that were refractory either temporarily or permanently to hematinic therapy. In 1943 Davidson, Davis and Innes published a series of papers entitled "Studies in Refractory Anaemia" which dealt with the problem of classification on the basis of examination of the bone marrow by sternal puncture and divided the anemias refractory to liver extracts into two main groups, namely (1) refractory anemias with hypocellular normoblastic marrows, and (2) refractory anemias with hypercellular megaloblastic marrows. Of particular significance was their finding that the prognosis was vastly different in the two groups. Thus, of 16 patients in Group 1, 11 died of progressive anemia within a few months, while of 16 cases in Group 2 all eventually made a complete recovery. Intensive treatment with large amounts of liver extract supplemented with iron and vitamins and repeated blood transfusions was required for long periods if such satisfactory results were to be obtained. The long period of illness during which life was continuously in danger indicated the need for some therapeutic agent which would cause a prompt remission comparable to that obtained with parenteral liver therapy in the relapse stage of Addisonian pernicious anemia.

In this paper the term refractory megaloblastic anemia is confined to cases of megaloblastic anemia which failed to respond hematologically and clinically to the parenteral administration of an amount of liver extract which has been proved to produce an optimal response in cases of Addisonian pernicious anemia. The test preparation employed was Anahaemin, marketed by British Drug Houses Ltd, which has been found by the writer to be potent in a dose of 2 cc when administered parenterally in a large number of cases studied during the past ten years. Every patient with refractory megaloblastic anemia received at least twice this dose after admission to hospital. In addition many cases had received large amounts of potent liver extracts prior to being referred to us for investigation of their failure to respond. Since infections, intoxications and advanced arteriosclerosis are known to inhibit or delay the response to parenteral liver therapy, patients exhibiting any of these complications were not included in the group of refractory megaloblastic anemia discussed below.

For many years the writer has suggested that chemical purification of liver extracts for parenteral use removes some essential factor which is necessary for the restoration of normal blood formation in certain cases of megaloblastic anemia which have failed to respond to potent liver extract given parenterally. The following case history of a patient seen by the writer nearly fifteen years ago illustrates this problem very clearly.

The patient was a middle-aged business man who had worked in India for many years and had always been in good health until one year before the present illness. His case notes from Calcutta indicated that

From the Department of Medicine, University of Edinburgh, Edinburgh, Scotland

a year previously he had had an attack of dysentery from which he apparently recovered completely. A few months later he began to feel tired and breathless on exertion. His tongue became sore and his bowels loose. The report from a medical specialist in Calcutta indicated that he had a moderate degree of macrocytic anemia and free hydrochloric acid was present in the gastric juice. Despite all treatment, he continued to lose weight and strength rapidly and was sent home to Scotland for investigation of the cause of his illness. When I first saw the patient he was extremely emaciated having lost 6 stone in weight during the previous twelve months. He was passing pale, greasy, bulky stools and the blood picture was typical of Addisonian pernicious anemia. His red cells numbered 1 M. and his Hb. 25 per cent. A histamine-fast achlorhydria was present. He was diagnosed as suffering from tropical sprue and given a low fat diet supplemented by vitamins and iron. Parenteral treatment with the liver extract Campolon was started. This resulted in a rise of reticulocytes to 15 per cent but no subsequent increase in red cells or Hb. occurred. The patient was desperately ill and life had to be maintained by blood transfusions. Parenteral liver therapy was continued but was totally ineffective. The patient's diet was then changed to a high protein diet containing 150 Gm. of protein daily in the form of meat and liver by mouth. Within a week a remarkable improvement in his general condition and hematologic state occurred. Within three months the patient gained nearly 4 stone in weight and his blood count and blood picture were restored to normal. Of particular interest was the finding that free hydrochloric acid was again present in his gastric juice. Contact was kept with this patient for many years and it was found that the complete clinical and hematologic remission was maintained.

This case represents a perfect example of a refractory megaloblastic anemia associated with the sprue syndrome which failed to respond to large quantities of crude potent liver extract given parenterally and showed a dramatic improvement when given liver by mouth.

During the next ten years I occasionally encountered patients with the classic pernicious anemia blood picture who were refractory to parenteral liver therapy but who responded to liver given orally. The problem of refractoriness was brought into prominence during an investigation which was conducted in Edinburgh into cases of pernicious anemia of pregnancy. In this group of megaloblastic anemias we found that refractoriness to potent liver extracts given parenterally is not uncommon. The results of the investigation were published in 1942 (Davidson, Davis and Innes). Of 16 cases with a classic megaloblastic marrow 10 were refractory to liver extracts given parenterally. Shortly after this investigation our attention was attracted to the megaloblastic anemias associated with the sprue syndrome (tropical sprue and idiopathic steatorrhea), and here again we found patients who were either completely or partially refractory to potent liver extracts given parenterally. In addition to cases of refractory megaloblastic anemia associated with pregnancy, and the puerperium and the sprue syndrome we also encountered cases of refractory anemia whose etiology was completely obscure, and to this group we gave the name 'idiopathic refractory megaloblastic anemia' and it is with this group that this paper is particularly concerned.

This short introductory note regarding our clinical investigations into refractory megaloblastic anemias over many years is given with the object of indicating why we desired to find a therapeutic agent which would be effective and why we believed that this product could be produced from liver which had not been submitted to a process of chemical purification for parenteral therapy.

The first step in this investigation consisted of predigesting liver with the enzyme papain at a pH of 5.6, thus avoiding the danger of destruction of active principles

by exposure to acid or alkaline conditions. The product obtained was a light brown powder completely soluble in water. The name "proteolysed liver" was selected for descriptive purposes. Since the walls of the liver cells had been completely disrupted it appeared likely that a high proportion of water soluble constituents would be liberated and hence retained in the final product, and that other active principles present as a protein complex would be set free and so be rendered available for immediate absorption. Clinical tests made with a 70 per cent alcohol soluble fraction of liver before and after digestion with papain supported this conclusion.

It was estimated that 1 oz. of "proteolysed liver" was derived from 6 oz. of raw "wet" liver. The material which has since been marketed under the trade name "Hepamino" was first tested on 5 cases of classic Addisonian pernicious anemia and produced a dramatic response in all instances in a daily dose of $\frac{1}{4}$ to $\frac{1}{2}$ oz. A report on the method of preparation and its clinical trial was published in 1943 (Davis, Davidson, Riding and Shaw). During the next two years work was extended to testing the preparation in cases of refractory megaloblastic anemia. Thus, in 1944, we described the remarkable results produced in 4 cases of idiopathic megaloblastic anemia and in 1 case of refractory megaloblastic anemia of pregnancy (Davis and Davidson). We also noted its therapeutic failure in cases of macrocytic anemia with a normoblastic marrow.

We suggested as a provisional hypothesis that "While failure of maturation of the megaloblasts in the great majority of megaloblastic anemias is due to deficiency of the liver principle of Castle present in fractionated liver extracts, in refractory megaloblastic anemias it results from an additional deficiency consequent on a failure in production or absorption of some unknown factor which is present in adequate amount and assimilable form in proteolysed liver and presumably also in whole liver." In the same paper we discussed the possible nature of this factor and came to the conclusion that it was unlikely to be a mineral, an amino acid, or any of the vitamins available at that time for clinical use. We suspected that it might be folic acid or biotin, both of which were known to be present in considerable quantities in liver. From our assessment of the position we felt that folic acid was most likely to be the missing factor and accordingly, in 1944, we wrote to Dr. Riding of Evans Medical Supplies Ltd., asking him to make a preparation of folic acid for clinical trial in refractory megaloblastic anemias. The folic acid fraction sent to us for this purpose consisted of material precipitated by 70 per cent alcohol from a watery extract of liver. This fraction is discarded in the manufacture of parenteral liver extracts as it has been repeatedly shown to be impotent therapeutically. Nevertheless, it is in this fraction that most of the folic acid in liver is stated to occur, as determined by biologic assay. As was to be expected from previous clinical experience, this fraction was found to be impotent when fed in daily doses of 1 oz. to patients with pernicious anemia. Unfortunately at that time no suitable case of refractory megaloblastic anemia was available on which to try the extract. These results suggested that if folic acid was present in the nonproteolysed 70 per cent alcoholic precipitate of liver, it existed in some conjugated form which could not be utilized by a patient with pernicious anemia or, alternatively, that

the content of folic acid in the test dose of extract was insufficient. The next step taken was to submit the 70 per cent alcoholic precipitate of liver to papain digestion and see whether this would lead to the liberation of some hematinic factor which was not available in the nonproteolysed 70 per cent alcoholic precipitate. Three cases of Addisonian pernicious anemia were treated with this proteolysed fraction. Of these, 1 case responded moderately well and 2 failed to show any response. The single success achieved suggested that as a result of enzymic digestion some potent material had been liberated but that the amount so liberated was insufficient to produce satisfactory results. From an assay of folic acid in proteolysed liver carried out at a later date, this supposition was almost certainly correct. Accordingly we decided to obtain a more potent source of folic acid and were in the process of investigating measures to achieve this object when the synthesis of folic acid was announced by Angier et al (1945) and its clinical and hematologic effects in megaloblastic anemias were published by Spies et al (1945). Through the courtesy of Messrs Lederle and Dr Spies, we were fortunate in obtaining adequate supplies of folic acid and have thus been able to confirm the observations made by Spies and other workers in America in regard to its effectiveness in all forms of megaloblastic anemia (Davidson and Girdwood, 1946, 1947). Of particular interest to us was the determination of the smallest dose of synthetic folic acid which would produce a hematologic response in pernicious anemia as this was obviously a matter closely related to the problem of what constituent in proteolysed liver was responsible for its therapeutic activity in megaloblastic anemias refractory to potent parenteral liver extracts. In this connection we should mention that of 5 cases of pernicious anemia treated with 2.5 mg of folic acid daily all responded satisfactorily. Of 5 cases given 1 mg daily 1 gave an excellent response, 2 a moderate response and 2 gave no response. The last 2 cases subsequently responded well to a daily dose of 2.5 and 5.0 mg respectively. The problem of the minimal effective dose of folic acid is referred to again in the discussion.

IDIOPATHIC REFRACTORY MEGALOBlastic ANEMIA

During the past six years more than 450 cases of macrocytic anemia have been submitted to a full clinical and hematologic examination including sternal biopsy in the wards and blood clinics under my charge. Approximately 75 cases out of this group were found to be cases of macrocytic anemia with a normoblastic marrow and need not be considered in this paper. They included many examples of the sprue syndrome and cases of chronic hepatitis, aplastic and hypoplastic anemia, macrocytic hemolytic anemia and aleukemic leukemia. Three hundred and fourteen cases were diagnosed as classical pernicious anemia and all responded satisfactorily to parenteral liver therapy, proteolysed liver or folic acid. In addition, parenteral liver therapy was effective in 12 cases of megaloblastic anemia associated with pregnancy and the sprue syndrome. Lastly there were 59 cases of megaloblastic anemia refractory to potent parenteral liver extracts. Since a description has been given in our previous publications of cases associated with pregnancy and the puerperium and with the sprue syndrome it has been decided merely to illustrate representative cases of these groups with graphs showing the effect of treatment.

FIG 1 A woman, aged 37, with refractory megaloblastic anemia associated with idiopathic steatorrhea. Response to folic acid (See Case History 2.)

FIG 2 Male, aged 32, with refractory megaloblastic anemia associated with tropical sprue. Response to folic acid

with proteolysed liver and folic acid (figs 1, 2 and 3), and confine our observations essentially to the group which we have called "idiopathic refractory megaloblastic anemia"

A patient is placed in this group only if the cause of the megaloblastic anemia cannot be ascribed to direct dietary deficiency, pregnancy or the puerperium, malabsorption from the gastrointestinal tract or hepatic disease. It is obvious that the more thorough is the investigation and the more prolonged the period of observation the fewer will be the cases which will be classified as idiopathic. This point is well illustrated by the following 2 case histories

FIG 3 * Refractory megaloblastic anemia associated with pregnancy. Response to proteolysed liver

CASE HISTORY I

First admission A man, age 61. He gave a two years history of weakness, breathlessness and anemia but there was no history of diarrhea, of paresthesia, of unsteadiness in walking, or of pain in the tongue. His diet had been satisfactory. A diagnosis of pernicious anemia was made in a neighboring hospital and the patient received 24 cc of a potent purified liver extract (Anahaemin) during a period of four weeks. The patient's condition continued to deteriorate so he was transferred to our clinic for further investigation and treatment.

When admitted the patient was very weak. His blood figures were as follows: Hb 28 per cent, R B C 950,000 per cu mm, W B C 5,200 per cu mm, P C V 13.0 per cent, M C V 136.8 cu microns, M C H C 30.0 per cent, reticulocytes 2.2 per cent, C I 1.5. The marrow was megaloblastic and a test meal showed that free hydrochloric acid was present. No other abnormality was found and at no time during the period of the first admission to our wards did the patient suffer from looseness of the bowels. He was treated with 20 mg of folic acid daily and this resulted in a reticulocyte peak of 18.2 per cent, a rapid gain in red cells and transformation of the marrow to the normoblastic state. Eventually the red cell count reached a level of 5 million. A diagnosis of idiopathic refractory megaloblastic anemia was made.

* Figures 3 and 4 previously appeared in *Pernicious Anemia and Other Megaloblastic Anemias*, L. S. P. Davidson and L. J. Davis, in *Advances in Internal Medicine*, New York, Interscience Publishers, Inc., 1947, vol. II, pp. 481-547. Reproduced by permission of the publishers.

Second admission The patient returned to hospital a year later because his ankles were painful and swollen. He had been having repeated courses of folic acid and the red cell count was moderately satisfactory, being 4,110,000 per cu mm. Examination of the stools revealed that he was now passing two large motions daily and these were pale, greasy and bulky. A fat balance test was carried out and this showed that the patient was absorbing only 59 per cent of ingested fat (normal 90 to 95 per cent). This clearly indicated that the patient was suffering from a malabsorption syndrome and accordingly the diagnosis was revised to that of idiopathic steatorrhea.

CASE HISTORY 2

First admission A woman, age 37. Admitted to hospital in March, 1944, when she was five months pregnant. Her hemoglobin was then 56 per cent and red cells 2,050,000 per cu mm. The bone marrow was megaloblastic. A test meal showed the presence of free hydrochloric acid. A diagnosis of pernicious anemia of pregnancy was made. She failed entirely to respond to 4 cc of Anahaemin given intramuscularly, but responded to proteolysed liver, an increase of red cells of one million per cu mm occurring in twenty days. The patient was then discharged from hospital, but owing to difficulty in obtaining proteolysed liver she did not continue treatment.

Second admission She was readmitted in April, 1946, with a history of weakness and of intermittent diarrhea of a fatty type, a fat-balance test showed the percentage absorption to be 75 per cent. A test meal again showed the presence of free hydrochloric acid. She had never been abroad, and the dietetic history was normal. No antianemic treatment had been given for eighteen months before the commencement of folic acid therapy. At the start of folic acid therapy her blood findings were as follows: Hb 40 per cent, red cells 1,370,000 per cu mm, white cells 7,800 per cu mm, P C V 19.0 per cent, M C V 138.7 cu microns, M C H C 28.9 per cent, reticulocytes 3.5 per cent, C I 1.5.

The reticulocyte response and the rise in red cells over a therapeutic period of 14, 21 and 28 days reached the standards demanded by the U S P Board (see fig 1).

A diagnosis of idiopathic steatorrhea was made.

These case histories, together with others which we do not think it is necessary to elaborate, suggest that a failure in absorption from the alimentary tract may be a primary fault in some cases of idiopathic megaloblastic anemia. In a few of these patients the poor bodily build and lack of development of the skeleton suggested previous malabsorption from the gastrointestinal tract though no history of diarrhea could be obtained at any time from infancy up to the presenting illness. The absence of such a history may have little significance since we have clearly demonstrated in the sprue syndrome that fat absorption may remain grossly defective although diarrhea is absent and the patient's general health is good either as a result of folic acid therapy or from spontaneous remission (Davidson, Girdwood, and Innes, 1947). Other possible causes of alimentary dysfunction which are worthy of consideration are an abnormal intestinal flora or chemical or enzymic secretory defects which destroy the antianemic factor or fail to liberate it from its bound form in natural foods.

Some of the clinical and hematologic features of the group of cases labelled idiopathic refractory megaloblastic anemia are given in table 1. The patients were of both sexes and their ages ranged from 12 to 76 years. The chief complaint in all cases was weakness and breathlessness on effort, and physical examination usually revealed nothing of importance other than the signs and effects of severe anemia. Acute glossitis and objective signs of involvement of the central nervous system were absent. Chronic glossitis was frequently noted. The liver, spleen and lymphatic glands were not enlarged. The blood picture and the bone marrow were

identical with that seen in Addisonian pernicious anemia at corresponding levels of anemia, except in Cases 16, 17, 18 (see table 1) In those cases with histamine-fast achlorhydria the differential diagnosis from pernicious anemia was impossible

TABLE 1—Cases of Idiopathic Refractory Megaloblastic Anemia

Case no	Sex	Age	Free HCl	Before treatment		Treatment given	Initial hematologic response to treatment
				Hb %	Red cells (mill/cu mm)		
1	M	46	Absent	28	1 17	Intensive liver, iron, ascorbic acid, transfusion	Slow and delayed

Cases 16, 17, 18 These 3 cases had a dimorphic bone marrow. Although some typical megaloblasts were present the majority of the erythroblasts were normoblasts or cells intermediate in appearance between megaloblasts and normoblasts.

Case 19 Owing to vomiting this patient was initially unable to take adequate quantities of proteolysed liver.

until their failure to respond to parenteral injections of potent liver extract was discovered. In other cases the presence of free hydrochloric acid in the gastric juice was a point of exceptional diagnostic importance. Such cases would conform to the

FIG 4 Idiopathic refractory megaloblastic anemia in a 12 year old girl Response to proteolysed liver

FIG 5 Idiopathic refractory megaloblastic anemia in a man aged 53 Response to folic acid

diagnosis of achrestic anemia as defined by Israels and Wilkinson (1936, 1940) When the disease occurs in patients below the age of 30 and is not associated with pregnancy, suspicion should be aroused that the case is not one of classic pernicious anemia Likewise, if the state of nutrition is unsatisfactory and the skeleton poorly developed a malabsorption syndrome should be suspected As has already been emphasized the patients were only placed in the idiopathic group when search for a cause for the anemia had failed to establish any satisfactory etiological explanation With regard to treatment it should be noted in table 1 that cases 1 to 9 were under our care prior to the advent of proteolysed liver and folic acid They had a prolonged and dangerous illness lasting weeks or months and many would have succumbed if life had not been supported by repeated blood transfusions while intensive treatment with parenteral liver extract, iron and vitamins was continued Cases 10 to 21 were treated with proteolysed liver, and cases 21 to 25 with folic acid Case 21 was treated successfully in his first relapse with proteolysed liver A second relapse, resulting from cessation of treatment, responded excellently to folic acid In contrast to cases 1 to 9 whose response to treatment was slow and prolonged, cases 10 to 25 responded to proteolysed liver or folic acid in a manner comparable to that obtained in pernicious anemia with parenteral liver extract therapy Representative examples of these cases are shown in figures 4 and 5

DISCUSSION

The parenteral injection of chemically purified liver extracts and the oral administration of liver, liver extracts, proteolysed liver and folic acid produce identical effects in transforming the megaloblastic bone marrow of Addisonian pernicious anemia into the normoblastic state as has been clearly demonstrated by studies of the bone marrow by ourselves and other workers It may therefore be assumed that some common factor is responsible for this effect Since daily doses of 1 mg. of synthetic folic acid will accomplish this result it appears likely that folic acid itself is the maturation factor, or plays some essential role in the final stage of the process of maturation Since purified liver extracts for parenteral therapy are practically devoid of folic acid it seems not unreasonable to suppose that they produce a transformation of the bone marrow through their ability to liberate free folic acid from its conjugated state Hence it may be postulated that in pernicious anemia the inability of the stomach to produce Castle's intrinsic factor leads to a failure in the production of an interaction product whose function is to liberate free folic acid There appears to be no failure in the absorption of conjugated folic acid since an immediate response is obtained to the injection of purified liver extract even when the patient has been partaking of an unsatisfactory diet for long periods

In contrast the refractory megaloblastic anemias may be considered to be due to a failure in the supply of conjugated folic acid since no response occurs to the injection of large doses of potent purified liver extract This failure of supply may result from direct nutritional deficiency as occurs particularly in tropical countries such as India (Lucy Wills, 1931) and the anemia may be partially or completely refractory to large doses of purified liver extract given parenterally Other cases can be explained on the basis of a malabsorption syndrome as is typically seen in tropical

sprue and idiopathic steatorrhea (see figs 1 and 2) As has already been noted some of these cases may not be recognized because a failure in absorption can occur in the absence of diarrhea In other cases the possibility exists that abnormalities in the intestinal flora, or chemical and secretory changes in the alimentary tract may destroy folic acid or make it unavailable to the body in some way as yet unknown

Lastly the liver plays an important role in the storage and possibly the final synthesis of the liberating factor formed from the interaction of Castle's intrinsic and extrinsic factors It may also be of importance in the storage and liberation of free folic acid Accordingly it is not surprising that in severe chronic disease of the liver a megaloblastic anemia is occasionally found In our experience, however, the macrocytic anemia of hepatic disease is accompanied much more frequently by a normoblastic marrow reaction Accordingly it may be concluded that a deficiency of conjugated folic acid can result from a variety of causes, some of which are known while others can merely be suspected The resulting megaloblastic anemia will be partially or completely refractory to parenteral liver extracts depending on the relative degree of deficiency of conjugated folic acid All types of megaloblastic anemia respond to the administration of free folic acid This is not surprising since by giving free folic acid the need for an interaction to take place between the liberating factor contained in purified liver extracts and conjugated folic acid contained in food is circumvented What is surprising is the dramatic therapeutic effect produced by the oral administration of folic acid in the malabsorption syndromes such as sprue We can only assume that the capacity to absorb different substances in this syndrome varies greatly Thus absorption of fat appears to be particularly poor while the absorption of free folic acid must be nearly perfect since a daily dose of 5 mg or less will produce the most dramatic clinical and hematologic improvement in sprue cases with a megaloblastic anemia

Lastly it is necessary to consider why proteolysed liver is usually as effective in the treatment of refractory megaloblastic anemia as is free folic acid

Proteolysed liver contains the liberating factor present in chemically purified liver extracts for parenteral use Experience has shown, however, that oral treatment with whole liver is very much less effective than parenteral treatment with liver extract derived from an equivalent amount of liver

The therapeutic effects of proteolysed liver in refractory megaloblastic anemia cannot therefore be ascribed to its content of this factor Proteolysed liver is a rich source of amino acids readily available for absorption because of the predigestion of liver protein with papain We have treated cases of pernicious anemia with a papain digest of beef protein without any response, and hence do not think it likely that the therapeutic activity of proteolysed liver depends on its content of amino acids It is possible, however, that liver contains some amino acid in high concentration which is necessary for the maintenance of normoblastic blood formation No evidence of this hypothesis is, however, available Supplementing the diet with individual amino acids such as methionine and choline has not been found effective in the treatment of the megaloblastic anemias Proteolysed liver is a rich source of many vitamins, especially of the vitamin B complex including folic acid The question therefore arises whether the therapeutic effects of proteolysed liver can be

ascribed to its content of folic acid. Before this question can be answered it would be necessary to undertake an assay of its folic acid content by the biologic methods at present in use. Opinion appears to differ widely among experts whom we have consulted in regard to the accuracy of such methods when used for the estimation of folic acid in foods and tissues. The only figures which we have available have been supplied to us by Dr. Riding of Evans Medical Supplies Ltd., who found an average figure of 0.8 mg. of folic acid per oz. of proteolysed liver. This quantity approaches the lowest amount of synthetic folic acid which we have found to be effective in the treatment of Addisonian pernicious anemia. As previously noted, of 5 cases given 1 mg. a day only 1 gave an optimal response, 2 showed no response and 2 showed a moderate response. In contrast the first 5 cases of pernicious anemia treated with proteolysed liver in doses of less than $\frac{1}{2}$ oz. daily (folic acid content 0.4 mg.) all showed an optimal response. It may be safely concluded that the therapeutic effect of free folic acid must have been augmented by other hematinic principles contained in the preparation, e.g. the liberating factor and possibly other members of the vitamin B complex. The lowest dose of folic acid which we have used for the treatment of refractory megaloblastic anemia is 2.5 mg. daily and this dose was effective in the only case in which it was tried, hence we are unable to state what is the minimal effective therapeutic dose in this group of anemias. Even if it be assumed that it is in the region of 1 mg. daily the results achieved by 1 oz. of proteolysed liver daily in refractory megaloblastic anemia were superior to that produced by 1 mg. daily of synthetic folic acid in pernicious anemia. Accordingly we feel that the beneficial effects of proteolysed liver in refractory megaloblastic anemias cannot be explained solely on its content of folic acid, nor on its content of the liberating factor since large amounts of purified liver extract given parenterally are ineffective.

The superior efficiency of orally administered liver or proteolysed liver to liver extract given parenterally in refractory megaloblastic anemia can be explained on one or other of the following hypotheses: (1) That some interaction takes place in the gastrointestinal tract between the ingested liver preparation and gastrointestinal enzymes which leads to a potentiation of hemopoietic factors already present, or (2) that liver and proteolysed liver contain some essential hemopoietic principles, including folic acid and possibly other members of the B₂ complex, which are removed or destroyed in the chemical processes used in the manufacture of liver extracts for parenteral injection.

Additional support for this latter view is suggested by the following observations. We have many cases of tropical sprue and idiopathic steatorrhea who persistently have a moderate degree of macrocytic anemia which is entirely resistant to parenteral liver therapy. The bone marrow presents a picture which is mainly normoblastic but many erythroblasts have an appearance intermediate between a megaloblast and a normoblast. The failure of parenteral liver therapy and iron to restore the marrow picture to normal and the persistence of a macrocytic anemia clearly indicate a lack of some additional hematinic factor. The hope that this factor would be folic acid was not realized as can be clearly seen in the

protocols of our cases published in 1946 (Davidson, Girdwood, and Innes) Proteolysed liver also was found to be ineffective in some of these cases of refractory macrocytic anemia associated with the sprue syndrome In 2 or 3 cases, however, it caused a considerable increase in the blood level after parenteral liver therapy and folic acid by mouth had failed In such cases we concluded that proteolysed liver contained some additional hematinic principle whose composition was still unknown An investigation into the nature of this principle is proceeding Our therapeutic program in operation at the present time is based on the investigations detailed above Our practice is to treat all cases of megaloblastic anemia in the first instance with parenteral liver extracts Should the result be unsatisfactory we prescribe folic acid If this fails to restore the blood picture to normal we give 1 oz of proteolysed liver daily By this means we are able to restore the blood picture qualitatively and quantitatively to normal in the great majority of cases of megaloblastic anemia of all types

SUMMARY

1 Fifty-nine cases of megaloblastic anemia refractory partially or completely to potent liver extracts given parenterally have been investigated in Edinburgh during the past six years Thirty-four of these cases were associated with pregnancy, the puerperium or the sprue syndrome No explanation of the cause of the megaloblastic anemia was discovered in the remaining 25 cases

2 The etiology, clinical features and treatment of 25 cases of idiopathic refractory megaloblastic anemia are described Attention is directed to the excellent therapeutic effects produced by proteolysed liver or folic acid

3 The mechanisms involved in refractoriness to potent parenteral liver extracts are discussed

4 In certain cases of refractory megaloblastic anemia it is suggested that an unknown hematinic principle, in addition to the liberating factor in purified parenteral liver extract and folic acid, is required for the complete restoration of normoblastic blood formation

ACKNOWLEDGMENTS

My thanks are due to many members of my staff who have helped in these investigations, particularly to Professor L J Davis formerly lecturer in Medicine in the University of Edinburgh, and to Dr Girdwood Grateful acknowledgment must also be made to Doctor Riding, Medical Director of Evans Medical Supplies Ltd and his research chemists who were responsible for the preparation of proteolysed liver and the other fractions of liver mentioned above

FURTHER OBSERVATIONS ON THE SPECIFICITY OF THE FOLIC ACID MOLECULE

By TOM D SPIES, M D , GUILLERMO GARCIA LOPEZ, M D , ROBERT E STONE, M D ,* FERNANDO MILANES, M D , ROBERT O BRANDENBURG, M D ,* AND TOMAS ARAMBURU, M D

IT HAS been established that pteroylglutamic acid (folic acid) stimulates the development of white blood cells, red blood cells and platelets in a variety of animal species and in persons who have certain types of macrocytic anemia. Our studies of folic acid have been concerned chiefly with the striking hematologic response which follows its administration to persons with pernicious anemia, nutritional macrocytic anemia and tropical sprue in relapse. This response has been described in considerable detail,¹ and it has been pointed out that it is indistinguishable from that which follows the administration of refined liver extracts. Nevertheless, the potency of refined liver extracts is out of all proportion to the amount of folic acid they contain, and it is our working hypothesis that the hemopoietic factor in refined liver extracts differs chemically from folic acid per se. The study of the synthetic folic acid molecule offers great promise toward determining something of the nature of blood regeneration. Recently we showed² that patients who do not show a hematologic response to methyl folic acid will respond to the folic acid molecule. Since this study was reported, we have investigated the hemopoietic properties of six additional compounds, somewhat related to folic acid in their chemical structure, in persons with Addisonian pernicious anemia, nutritional macrocytic anemia and tropical sprue in relapse. This communication is concerned with these extended observations on the specificity of the folic acid molecule.

MATERIALS AND METHODS

From a large group of patients, 11 patients with macrocytic anemia were selected for study. Four of these were classified as Addisonian pernicious anemia, 3 as nutritional macrocytic anemia, and 4 as tropical sprue patients. In all cases megaloblastic proliferation and defective maturation, a red blood cell count of less than 2.5 million and a color index of more than 1 were essential diagnostic criteria. For a differential diagnosis of the type of macrocytic anemia, additional criteria were the absence of free hydrochloric acid in the gastric contents even after histamine stimulation in pernicious anemia and the presence of free hydro-

Northwestern University Studies in Nutrition and Metabolism at the Hillman Hospital, Birmingham, Alabama, and at the Calixto Garcia Hospital, Havana, Cuba, in cooperation with the University of Havana. From the Department of Nutrition and Metabolism, Northwestern University.

This study was made possible by grants from Lederle Laboratories, Inc. and The National Vitamin Foundation.

Valuable technical assistance was given by Miss Belle Culver, Miss Jane Davis and Mrs. Mary B. Koch.

* Williams-Waterman Fellow in Nutrition.

chloric acid in nutritional macrocytic anemia and sprue. Usually the patients with nutritional macrocytic anemia had diarrhea characterized by loose, dark stools. The diarrhea present in the patients with sprue was characterized by large, liquid to semisolid, foul-smelling stools, varying in color from whitish yellow to yellowish green. A diagnosis of sprue was not made in the absence of steatorrhea. The glucose tolerance curve tended to be flat in both nutritional macrocytic anemia and sprue, and loss of weight, which usually had occurred in both, tended to be greater in sprue than it was in nutritional macrocytic anemia. A history of subsistence on an inadequate diet over a period of years was given by all of the patients with sprue and nutritional macrocytic anemia.

All the patients were admitted to the hospital where thorough medical and dietary histories were obtained and a complete physical examination was made. Rigid dietary control was instituted on admission and continued throughout the duration of the study. Meat, meat products, fish and poultry were excluded. Only 1 pint of milk, 1 hard cooked egg and 3 level teaspoons of butter were allowed daily. Raw vegetables were excluded and all other vegetables were served overcooked. All other foods were allowed in any amount desired.

FIG. 1. FORMYL PTEROYL GLUTAMIC ACID (FORMYL FOLIC ACID)

For both the white cell and erythrocyte counts, certified Trenner pipets were used. The hemoglobin content of the blood was determined in grams by means of a Leitz or an Evelyn colorimeter. The reticulocytes were counted in wet preparations by the use of a modified brilliant cresyl blue solution of Dameshek. In all cases permanent fixed preparations of blood smears were made just prior to treatment, and once or twice a week thereafter cell volumes were determined on oxalated venous blood by means of Wintrobe hematocrit tubes. Prior to treatment, bone marrow was obtained and again at the peak of reticulocytosis, and still another specimen was obtained when the reticulocyte count returned to normal. Differential counts were made on preparations stained with both supravital and Wright-Giemsa stains.

After baseline determinations were completed, 20 mg of the Mg salt of formyl pteroyl glutamic acid (see fig. 1) was administered orally to 1 patient with pernicious anemia and to 1 patient with nutritional macrocytic anemia for ten days. Twenty mg of the Mg salt of formyl pteroyl glutamic acid (S. lactis factor) (see fig. 2) was administered orally to 1 patient with pernicious anemia for ten days. Twenty mg of N-(4-(4-quinazoline) amino) benzoyl-glutamic acid (see fig. 3) was given orally to 1 patient with pernicious anemia for ten days. Then the dose was increased to 50 mg daily for five days. Twenty mg of pteroyl aspartic acid (see fig. 4) was given orally to 1 patient with tropical sprue for ten days, and 40

FIG 7 LIVER L CASEI FACTOR

N-[4-{[(2-amino-4-hydroxy-6-pteridyl)methyl]amino}benzoyl] glutamic acid

mg was given daily for an additional ten days. Another patient with tropical sprue was given 20 mg orally for ten days. Twenty mg of oxyfolic acid (see fig 5) was

given daily by mouth to one patient with nutritional macrocytic anemia and to 1 patient with pernicious anemia for ten days. Twenty mg of oxypteroic acid* (see fig 6) was given daily by mouth to 2 patients with tropical sprue. If, within ten days, reticulocytosis had not occurred, 10 mg of folic acid (see fig 7) was administered until the blood values reached satisfactory levels.

RESULTS

Response to Mg Salt of Formyl Pteroyl Glutamic Acid Following the administration of this material to the patient with pernicious anemia, the reticulocytes began to rise on the seventh day and reached a peak of 9.6 per cent eleven days after its administration was initiated. This was followed by a slight increase in red blood

FIG 8 Comparative response to folic acid and Mg salt of formyl pteroyl glutamic acid in a patient with addisonian pernicious anemia

cells, hemoglobin, white blood cells and platelets. The response, however, was poor compared to his response to the administration of folic acid per se during another comparable relapse of the disease when his reticulocytes began to rise on the fourth day of therapy and reached a peak of 39.8 per cent on the eighth day (see fig 8). By the end of ten days there was an increase in white blood cells and platelets. The response of the patient with nutritional macrocytic anemia to Mg salt of formyl pteroyl glutamic acid was slightly greater, but it was not of the magnitude which followed folic acid per se. Following the administration of Mg salt of formyl pteroyl glutamic acid, the reticulocytes began to rise on the fourth day and reached a peak of 25.4 per cent on the tenth day, whereas on folic acid per se,

* The Mg salt of formyl pteroyl glutamic acid and the Mg salt of formyl pteroyl glutamic acid were furnished by Dr Y SubbaRow of Lederle Laboratories, Inc. The N-(4-(4-quinazoline) amino) benzoyl)-glutamic acid, the pteroyl aspartic acid, the oxyfolic acid and the oxypteroic acid were furnished by Dr Gustav Martin of The National Drug Company. Only small quantities of these compounds were available so that in no instance did we have an opportunity to test the effect of massive doses.

which was administered during another, but comparable, relapse of the disease, the reticulocytes began to rise on the third day and reached a peak of 60.4 per cent on the eighth day (see fig 9). There was a slight rise in the red blood cells, hemoglobin, white blood cells and platelets following the administration of the Mg salt of formyl pteroyl glutamic acid but they did not reach satisfactory levels until folic acid therapy was initiated.

Response to Mg Salt of Formyl Pteroyl Glutamic Acid (*S. lactis* Factor) The administration of this material in the dosage given did not produce blood regeneration in a patient with pernicious anemia, whereas an excellent response followed the administration of folic acid *per se*.

Fig 9 Comparative response to folic acid and Mg salt of formyl pteroyl glutamic acid in a patient with nutritional macrocytic anemia

Response to N-(4-(4-Quinazoline) amino) benzoyl)-Glutamic Acid Neither the patient with pernicious anemia nor the one with nutritional macrocytic anemia had any hematologic response to this material at the dosage level used. On subsequent therapy with folic acid an excellent response was observed.

Response to Pteroyl Aspartic Acid Blood regeneration did not follow the administration of this material at the dosage level given in either of the 2 cases of tropical sprue. Both these patients later showed a good response to folic acid.

Response to Oxyfolic Acid The administration of this material produced no blood regeneration in the patient with pernicious anemia or in the one with nutritional macrocytic anemia at the dosage level administered. Subsequent treatment with folic acid was followed by an excellent response.

Response to Oxypteroyl Acid At the dosage level used, blood regeneration did not follow the administration of this material in two cases of tropical sprue, whereas folic acid therapy which was given later produced an excellent response.

SUMMARY AND CONCLUSIONS

Methyl folic acid,² N-(4-(4-quinazolinyl) amino) benzoyl)-glutamic acid, the Mg salt of formyl pteroyl glutamic acid, the Mg salt of formyl pteronic acid, pteroyl aspartic acid, oxyfolic acid and oxypteronic acid have been studied as to their effect on blood regeneration in selected cases of Addisonian pernicious anemia, nutritional macrocytic anemia and tropical sprue. In the amounts administered, only the Mg salt of formyl pteroyl glutamic acid was effective in producing reticulocytosis and an increase in red blood cells, hemoglobin, white blood cells and platelets, and it was not as effective per unit of weight as was folic acid per se. Presumably this compound is slowly changed into folic acid in the body. It is of special interest that the Mg salt of formyl pteronic acid (*Streptococcus lactis factor*) was negative in producing hemopoiesis. These observations show the very great specificity of the folic acid molecule.

CASE REPORT

A CASE OF PERNICIOUS ANEMIA REQUIRING ENORMOUS AMOUNTS OF LIVER, ESPECIALLY BY MOUTH, OVER TWENTY YEARS

By ROGER I LEE, M D

I STILL believe that there is a place for the occasional case report in medical literature. A disease like pernicious anemia, with its protean manifestations and wide variations of course, presents difficulties in the way of statistical presentation. I have used the present case for clinical demonstration a number of times. If we both live, her case may be continued.

At first I used to demonstrate this patient, who needed a large amount of liver over a good many years for the treatment of pernicious anemia, as a contrast to another patient who needed liver only once a month or so. There was, I think, no possible doubt of the diagnosis in the 2 cases, but the contrasting case unfortunately died of an intercurrent disease.

REPORT OF CASE

The case which I report is that of a woman who was seen first in March 1925. She was a school teacher, then 39 years of age. She had symptoms of fatigue and weakness, with irregular fever beginning in 1923. When she was first seen, the platelets were very much increased and a positive diagnosis of pernicious anemia was not made until August 1925. The feature of her early course was a continued fever. She was put on a diet of raw liver, but escaped observation by going to another part of the country where liver was discontinued. In 1928 she developed trouble with her legs. In 1929, she presented a fairly typical ataxic paraplegia. She was given one-half pound of raw liver a day with a great deal of improvement in her ability to walk, although she still presented the clinical picture of ataxic paraplegia. Since this episode and to the present time, she has required a very large amount of liver. She has had liver in every available form. If she did not have some liver by mouth and tried to depend entirely upon injections of liver, slowly she would develop headache, backache, and some slight difficulty with her bladder. When she increased the liver by mouth, these symptoms would slowly subside. All the time she was taking injections of liver extract, usually once a week and sometimes twice. During the war years when liver was difficult to obtain, this patient had a particularly hard time in securing the liver to be taken by mouth. She did very well on half a pound of beef liver (she could not take pig's liver) six days a week. That would represent a yearly intake of 150 pounds of liver, by mouth. This woman weighed only 100 pounds on the average, sometimes less and sometimes more. Consequently, she ate her weight in liver in a year and this was in addition to the injections of liver. In the twenty odd years which she has been under treatment, she has taken by mouth certainly over a ton of raw liver. In addition, we have given her iron, all forms of liver substitutes by mouth and every form of liver extract. None has had the same effect as the raw liver by mouth. We have given her vitamins, all without any appreciable effect. We have also given her folic acid and this too in addition to the injections of liver and what liver she can take by mouth. We have no final opinion on the effect of folic acid yet, but it does seem to be beneficial. During all this time, her hemoglobin has been running from 84 to 94 per cent and her red cell count four and a half to five million.

A very curious feature has been that she would develop headache, back pain and some increased disturbance of the bladder and in walking long before she showed any evidence of disturbance in her blood. Gradually, the blood would show evidences of a slight deterioration, but this was never very marked. The improvement of symptoms would anticipate by a month or two the improvement of her blood. These down dips in her symptoms were usually initiated by an intercurrent infection or some complication which made it difficult for her to get the additional liver to take by mouth.

Anyone who has studied pernicious anemia appreciates the wide variation in the spontaneous course of the disease. In this case, it is to be noted that fever was an early symptom and that this was by no means slight. I regard that as an indication of the intensity of the condition. The contrasting case, which I used to show with this patient, at no time had fever. Her condition seemed to be of a gentler kind. The patient in this contrasting case, in spite of the small amount of liver that she took, due to the fact that she felt well, never developed the lesions of pernicious anemia in the central nervous system. I think it has long been recognized that the more intense cases of pernicious anemia are more likely to have lesions of the central nervous system, although it is well known that all long-standing cases of pernicious anemia have at autopsy actual lesions in the central nervous system. Our patient developed symptoms of the central nervous system early. At one time, there was a great deal of discussion as to the efficacy of liver therapy in lesions of the central nervous system. This case would seem to indicate that liver therapy does not cause complete regression of the lesions of the central nervous system, but it keeps them under control.

At no time during these twenty years, has this patient had an enlarged liver, enlarged spleen, hypertension or particularly abnormal blood chemistry, although the non-protein-nitrogen was apt to be in the high 30's and the uric acid was apt to be around four.

This case indicates several things to me:

1. The variation in the intensity of the disease of pernicious anemia.
2. That involvement of the central nervous system is apt to indicate a disease that may be difficult to treat.
3. That some cases of pernicious anemia require relatively enormous amounts of liver therapy and that successful therapy may demand even in these days a combination of oral as well as intramuscular liver.
4. Finally, this case illustrates the fact that some cases of pernicious anemia present real problems in treatment and cannot be treated by any rule of thumb method.

THE SCHOENLEIN-HENOCH SYNDROME OF VASCULAR PURPURA*

By ELI DAVIS, M D

DEFINITION

THE Schoenlein-Henoch syndrome is a condition in which nontraumatic hemorrhage, with or without edema, occurs in the skin, or subcutaneous tissue, or joints, or viscera, or in any combination of them, and in which the blood platelets are normally abundant

The name Schoenlein-Henoch purpura is well established, yet the eponym is ill chosen (as so many eponyms seem to be) Willan¹⁴ described one type of the syndrome in a London publication in 1808, while a description of Schoenlein's disease was recorded not by Schoenlein himself but by one of his pupils in 1837¹¹ According to this description, the patients were often rheumatic sufferers, and they presented purpura, pains, and swellings, particularly in the knee and knuckle, but occasionally in the hand and shoulder joint Henoch's work appeared in 1868⁷ and he referred to 7 cases in a paper in 1874⁸ Apert¹ (1897) gave an excellent clinical description under the name of exanthematic purpura Osler,⁹ in 1914, in his paper, "The Visceral Lesions of Purpura and Allied Conditions," did much to clarify ideas on the condition, but his view that the anaphylactic key would unlock the mystery of these cases found too ready an acceptance

Numerous case reports have appeared, but most observers have described but few cases each and only a hazy idea of the natural history has emerged The description which follows is based on 44 personally observed cases seen in eight years, against a background of 1200 cases of purpura (mostly benign) An account of the first 500 of these cases has been given by Davis³ (1943)

SEX, AGE, DURATION

The condition was about three times as common in women as in men, but, in children, boys and girls were about equally affected Patients aged 4 to 71 were affected, but there were peaks of incidence of first attacks from 4 to 10 years old, and from 16 to 40 Half of the patients had had more than one attack, and half were seen in their first attack It is probable that about one third had had but one attack A few had had numerous attacks Each attack usually lasted for a few weeks Attacks had recurred over periods varying from a few months up to 50 years,

*From the Rothschild Hadassah University Hospital, Jerusalem Most of the cases on which this paper is based were seen in the service of the London County Council, but typical cases seen in Jerusalem are included

but in most patients they ceased within five years from the onset. Of the 44 cases, 5 patients were each members of different families with hereditary familial purpura simplex. No familial instances were encountered.

ETIOLOGICAL FACTORS

In 10 patients attacks were preceded by acute tonsillitis. In one patient, each of her three attacks was heralded by an acute tonsillitis. One patient suffered from

FIG. 1. Girl, aged 8 (a) Edema of eyelids and face (b) Petechiae of buttocks. Melena, hematuria, joint swellings

pulmonary tuberculosis and had two attacks. In another patient true acute cholecystitis preceded the attack. There was a history of acute rheumatic fever earlier in life in 4 patients, but in at least 2 of these patients the so-called acute rheumatism was almost certainly an earlier attack of Willan-Schoenlein-Henoch disease. Only 6 of the patients were affected with fibrositis. In 8 patients an antistreptolysin titer was done at the height of the disease, in 6 the titer was normal, and in 2 raised to 800 and 1250 units. (Several of the patients with acute tonsillitis had normal titers.)

TEMPERATURE

Only 11 patients were febrile during attacks. Three were febrile for one month, another had low grade fever for one year, a fifth had bouts of low grade fever lasting about a week every few months for over five years, and a sixth had persistent fever of up to $100-101^{\circ}$ for months at a time for the eight years she was under observation. Blood cultures were negative in all.

FIG 2 Girl, aged 7. Petechiae back of neck and shoulder, blood in cerebrospinal fluid, melenæ, joint swellings.

PURPURA, RASHES, EDEMA

Of the 44 cases, 38 showed spontaneous ecchymoses or petechiae or both. Most showed skin purpura only during attacks but a few had ecchymoses between attacks. The ecchymoses, which occurred mostly on the limbs, varied from $\frac{1}{2}$ –4 inches in diameter (fig 4) and were painless. Petechiae were seen, particularly over the skin of the buttocks and scapulae (figs 1 and 2), but the number of petechiae varied enormously, and the widespread rash with dense petechiae (fig 5) was rare. Petechiae were also seen in the mucous membrane inside the mouth and occasionally on capillary microscopy of the nail bed.⁴ In two patients the purpura

was in the form of a purpura nodosum, the erythema of erythema nodosum being replaced by purpura (fig 3) Melena was seen in 5 patients Epistaxis, hematemesis, and menorrhagia each occurred in 4 patients, hematuria in 3, mouth bleeding in one, blood was found in the cerebrospinal fluid of one patient with meningeal irritation⁵

Urticaria accompanied the attacks in 3 patients and 4 others had a papular or papulovesicular rash Localized edema occurred in the following order of fre-

FIG 3 Woman, aged 22 Ecchymoses of legs, purpura nodosum, hematuria, febrile one year, joint swellings

quency backs of hands, around the eyes, face (fig 1a), neck, lips, legs, arms, and penis

JOINTS, VISCERA

Joints particularly involved were those of the fingers, wrists, knees, elbows, and ankles Any one or any combination of these joints could be affected Joints were painful and nearly always swollen In some patients the edema was peri-articular and para-articular rather than in the joint itself Between attacks all affected joints recovered full function and did not ankylose, but in a few patients pain persisted Radiological changes did not develop

Gastrointestinal pain or hemorrhage was pronounced in 12 patients, while 3

patients had hematuria, a fourth casts and albuminuria without hematuria, and one patient gallbladder disease. Menorrhagia was present in 4 patients and uterine pains in a fifth. The spleen was not palpable.

GENERAL

The time relationship of the features of an attack was very variable. Petechiae, edema, joint pains, and visceral features often appeared within hours of one another, but skin petechiae at times preceded or followed other signs by an interval

FIG. 4. Woman, aged 40. Ecchymoses, febrile eight years, joint swellings.

of several days. Thus a puzzling visceral pain or joint swelling could be diagnosed only when a purpuric rash developed days later, or the nature of a purpuric rash might remain obscure until swollen fingers, orbital edema, and melena occur. In some cases, skin manifestations were absent entirely. By way of contrast, angioneurotic edema might be the sole feature of an attack. A classic illustrative case from this series has been described by Green.⁵

BLOOD FINDINGS

Blood counts, platelet counts, bleeding and coagulation times, clot retraction, and prothrombin time were normal but occasionally a polymorphonuclear leuco-

cytosis was seen. Blood sedimentation rate was usually normal, but occasionally high, likewise the antistreptolysin titer. When these were high there was also leucocytosis. The capillary resistance test was positive in only some 25 per cent of cases.

PROGNOSIS

The outcome for a particular attack and the ultimate outcome were good. Recovery was invariable, good health was enjoyed between attacks, and in most

Fig 5 Man, aged 30. Massive petechiae legs, hematuria, joint swellings

patients attacks rarely recurred after 5 years. The 4 patients with renal involvement had no residual lesions and made full recoveries despite the gloomy prognosis so often given to Schoenlein-Henoch purpura with renal complications. The child with the subarachnoid hemorrhage recovered completely.⁵ But some patients required treatment for hematuria or hematemesis or melena, which they naturally found alarming. Persistent fever in several patients was worthy of note, particularly in the case presenting pyrexia lasting for eight years. This experience demonstrates that Schoenlein-Henoch purpura must be added to the causes of persistent low grade fever.

DIFFERENTIAL DIAGNOSIS

It is clear that abundant opportunities for confusion with other diseases exist. Among the labels attached to cases I encountered were acute rheumatic fever, septicemia, subacute infective endocarditis, rheumatoid arthritis, infective arthritis, nephritis, bleeding peptic ulcer, and trichinosis. The differential diagnosis from palindromic rheumatism⁶ must also be considered. The cases of angioneural arthrosis described by Solis-Cohen¹³ (1914) may be identical with Schoenlein-Henoch purpura.

TREATMENT

Treatment was essentially symptomatic. Vitamin C was of no value, the preparations of vitamin P used were not beneficial, and vitamin K was not indicated. The patient with persistent attacks of fever for one year recovered after tonsillectomy. The patient with the eight years' fever was not helped by protein shock, auto-hemotherapy, blood transfusions, or sulphonamides. After the exhibition of penicillin an attack was cut short and she enjoyed three months of exceptional well-being, fever-free. But a second course of penicillin given for the relapse was ineffective. Spontaneous recovery had occurred after protracted attacks in the pre-penicillin era.

DISCUSSION

Most authors regard purpura simplex and Schoenlein-Henoch purpura as different facets of the same condition. By purpura simplex, I understand a condition in which ecchymoses with or without petechiae occur from time to time in the skin without any known trauma and without ascertainable cause. Now there is no doubt that one group of Schoenlein-Henoch cases is closely linked with purpura simplex—witness the occurrence of a case of Schoenlein-Henoch purpura in five different families of hereditary purpura simplex, while some cases of purpura simplex become almost indistinguishable from Schoenlein-Henoch purpura. The blood findings in both conditions are identical. There are distinct differences, however. Purpura simplex is overwhelmingly more frequent in women, is very often familial and is not common in children, but Schoenlein-Henoch purpura is not uncommon in males, is not familial and is quite common in children. One third of the patients with Schoenlein-Henoch purpura have only one attack, but single attacks of purpura simplex are much rarer. The fibrositic diathesis is much commoner in purpura simplex. My conclusion is that Schoenlein-Henoch purpura is a syndrome and not a disease and is a nonspecific reaction to different factors. The causes of purpura simplex and Schoenlein-Henoch purpura overlap but are not identical. One great cause of both conditions is recent infection by hemolytic streptococci. (It is possible that in some instances Schoenlein-Henoch purpura represents aborted or modified rheumatic fever, sparing the heart. Osler⁹ stated that rheumatic poison is believed to be responsible for a large group of these cases.) In most of my cases the cause was not found. In none of my cases of Schoenlein-Henoch purpura were food or drugs or known allergens found to be the cause,

but I would agree that allergic factors cause this condition occasionally. It is to be noted that no support for the anaphylactoid etiology was given by Bartley and Bell² (1936), Poncher¹⁰ (1935), and Siedlmayer¹² (1939). Osler⁹ was optimistic in his belief in the anaphylactic key, but he was right to insist that urticaria, angioneurotic edema, and vasomotor instability were all aspects of the same condition.

SUMMARY

The Schoenlein-Henoch syndrome is described on the basis of 44 personally observed cases. It is defined as a condition in which nontraumatic hemorrhage with or without edema may occur in the skin, or subcutaneous tissue, or joints, or viscera, or in any combination of them, and in which the blood platelets are normally abundant. The causes of the syndrome are varied, but streptococcal infection is important, and "anaphylactoid" causes rare. The prognosis is good, and the 4 cases with renal involvement also did well. Schoenlein-Henoch purpura and purpura simplex overlap, but in contrast with the latter, Schoenlein-Henoch purpura is not familial, and is common in males and children.

HYPERPROTHROMBINEMIA INDUCED BY VITAMIN K IN HUMAN SUBJECTS WITH NORMAL LIVER FUNCTION

By PAUL N. UNGER, M.D.,[†] AND SHEPARD SHAPIRO, M.D.

HYPERPROTHROMBINEMIA, as determined by reduction of prothrombin time below the range of normalcy, has been observed in man in cases of intravascular thrombosis and in animals after the administration of vitamin K.¹⁻⁹ The present study was undertaken to learn whether it is possible to induce hyperprothrombinemia in human subjects with normal liver function by the administration of large doses of menadione derivatives.

MATERIAL

Thirty-eight persons were studied. Students, house officers, and nurses made up 21 of the group. The remaining 17 were patients in whom liver function was normal. These were almost all cases of essential hypertension uncomplicated by circulatory or renal failure. All showed normal prothrombin time on repeated examinations. One case had amyloidosis in which a previous survey had yielded changes in prothrombin time pertinent to the present investigation. The data recorded below were obtained more recently.

METHOD OF PROTHROMBIN ASSAY

The procedure used was that described in earlier communications of the series.^{1, 8} It includes estimation of the prothrombin time of whole and diluted (12.5 per cent) plasma. For reasons given below, in 11 of the cases the prothrombin time of 8 per cent plasma was estimated. Venous blood was used exclusively. Each sample was freshly drawn and the plasma maintained in the water bath at 37° C for approximately fifteen minutes before the prothrombin time was estimated. All estimations were made in duplicate. The thromboplastin was prepared by vacuum desiccation of fresh rabbit lung. The end point was determined by lifting the clot, the instant it formed, away from the otherwise clear liquid by means of a tiny loop made of no. 22 nichrome wire.

PROCEDURE

The existing value of prothrombin time was established. Following this, synthetic vitamin K in the form of Hykinone* (Abbott) or Synkayvite† (Hoffmann-LaRoche) was administered by intravenous injection, and the prothrombin time was estimated daily for at least three succeeding days. In the cases in which no changes were detected, the experiment was continued for at least five days. Changes occurred in the diluted plasma prothrombin estimations only, and consequently the data presented below are confined to these figures.

From the Third (New York University) Division, Goldwater Memorial Hospital, Welfare Island, New York 17, and the Department of Medicine, New York University, College of Medicine, New York.

* Hykinone = 2-methyl-1,4 naphthohydroquinone sodium bisulfite.

† Synkayvite = 2-methyl-1,4 naphthohydroquinone diphosphoric acid ester tetrasodium salt.

‡ Present address, Miami Beach, Florida.

RESULTS

The data of the two groups are given below. In the first are 15 representative cases in which the 12.5 per cent plasma was studied and in the second are 7 subjects in which the 8 per cent plasma showed significant reduction of the prothrombin time after vitamin K medication.

The prothrombin clotting time was first estimated before the administration of the vitamin K preparation. When more than one figure was obtained, the arithmetic average of these figures was used. All were within the normal range. Prothrombin time estimations were made following the injection of the water soluble vitamin K preparation. The lowest prothrombin time after the injections was used to calculate the effect.

TABLE 1

	Prothrombin Time Mean	S D	S E _m
	sec		
I Before vitamin K	40.13	±2.92	±0.75
II Lowest after vitamin K	36.13	±2.68	±0.69
III 48 hours after last dose	39.25	±2.96	±0.76

S D = standard deviation

S E_m = standard error of the mean

TABLE 2

Difference	S E _{Diff}	C R
I and II 4.00	±1.02	3.9
I and III 0.88	±1.07	0.8
II and III 3.12	±1.02	3.2

Difference = difference between means of each group

S E_{Diff} = standard error of the difference

C R = critical ratio

The mean, standard deviation and the standard error of the mean were calculated for each group of figures. The difference between the mean of each group and the reliability of these differences was also calculated.

INTERPRETATION OF STATISTICS

The difference between the means of group I and II and of groups II and III is statistically reliable. From this we may conclude that there is less than one chance in a thousand that the difference is due to chance.

The difference between the means of groups I and III is not statistically reliable.

It is concluded that the effect of the administration of synthetic vitamin K was to reduce the prothrombin time significantly to the level of hyperprothrombinemia.

One advantage in using diluted plasma is to amplify the changes which occur

When the prothrombin time of whole plasma is estimated, clotting occurs so rapidly that fine alterations are obliterated. The dilution of 12.5 per cent has been used because it has been found by experience that it is highly sensitive, and because the end point in this dilution remains clearly discernible even in the presence of hypoprothrombinemia, such as is encountered after dicumarol medication and in liver disease. Dilution beyond 12.5 per cent and to 8 per cent, although adequate in normal plasma, has been found to be generally unsatisfactory when the prothrombin time is prolonged. In the present series we studied blood plasma of normal or accelerated prothrombin activity. Consequently the dilution of 8 per cent was used to amplify the changes in prothrombin time to a degree greater than that demonstrated in 12.5 per cent plasma. The end point in each case was clearly detectable.

Eleven subjects were given the treatment described above and changes in 8 per cent plasma noted. Seven yielded significant reduction of the prothrombin time while the remaining 4 showed no alteration in the prothrombin values. A statistical analysis of these data follows.

The data were divided into two groups. Group I consisted of the times required for clotting before the administration of vitamin K. Group II was the lowest prothrombin times after the antihemorrhagic quinone was given.

Since the group consists of only 7 cases, the data were treated differently from the series in which 12.5 per cent plasma was studied. The analysis of variance

method was used to compare the groups and the t value was calculated.¹⁰ The formula used was

$$\frac{(\bar{x} - m)}{S/\sqrt{N}}$$

where m is the hypothesized mean difference between the groups, \bar{x} the obtained difference between the groups, S the standard deviation of the mean difference, and N the number of cases. We make the initial assumption that there is no differ-

		Mean Diff	= 16 53
		S Diff	= 9 66
		<i>t</i>	= 4 5

Table I Calculating the *t* value to compare the difference between time required for clotting before and after the administration of vitamin K The *t* value obtained (4 5) was compared to the value of *t* at the 1 per cent level of confidence for 6 degrees of freedom ¹² The obtained *t* value of the 1 per cent level was 3 707, and this latter would be expected to occur only once in a hundred samples if *m* really were equal to zero difference between the two groups

CONCLUSIONS

The null hypothesis in this group of observations must be abandoned The difference between the two groups is highly significant at the 1 per cent level of confidence

DISCUSSION

The literature reflects a total lack of appreciation of the difference between changes in the hyper range and those occurring in the direction of hypoprothrombinemia To illustrate this, the following diagram is presented

Reduction in prothrombin time below the normal range (hyperprothrombinemia) meets with resistance of increasing magnitude as it progresses. Opposed to this is the prolongation of the prothrombin time, which proceeds with greater and greater ease as the degree of hypoprothrombinemia becomes more extensive. For example, a small dose of dicumarol will extend the prothrombin time from the hypoprothrombinemia level of sixty to eighty seconds, whereas a large dose is required to increase it from the original normal of forty seconds to sixty seconds. In contrast to this, it requires an agent of high potency to reduce the prothrombin time from the normal of forty to the hyperprothrombinemia level of thirty-six seconds, and to decrease it further meets with resistance of such proportions that it is accomplished with the greatest difficulty. Obviously, it is difficult to reproduce these changes by using methods of prothrombin estimation which employ whole plasma because clotting occurs so speedily that the fine changes are obliterated. Only by amplifying the differences by plasma dilutions can these changes, significant despite their relatively low magnitude, be detected.

It is important to note the difference in the pattern of hyperprothrombinemia as it arises spontaneously in certain clinical conditions (thrombosis, frost-bite, gangrene) and that induced by vitamin K. The clinical form continues for extended periods, whereas that induced by the antihemorrhagic substance is ephemeral. It appears that an additional mechanism enters the process when intravascular coagulation takes place, and it suggests at least a partial explanation for the tendency to multiple thrombosis.

It is not known whether or not in man other components of the blood which enter into the mechanism of coagulation vary in like manner after the giving of vitamin K. Work is now in progress in this laboratory to learn whether the fibrinogen and the thrombocytes alter under these conditions. It has been our experience in man that when we employed human fibrinogen in a concentration of 0.3 per cent as a diluent in place of normal isotonic saline that the values obtained, especially when diluted plasma was studied, were highly variable in normal as well as in pathological cases. Our original technic at the same time yielded results in serial estimations which varied within a very narrow range. In any event, if our subsequent findings reveal changes in the companion components of the coagulation system after vitamin K, then the present conception of the role of vitamin K will have to be extended.¹³

It is our belief that the behavior of the prothrombin-producing mechanism as revealed by the data presented in this communication is an expression of functional limitation and not a mathematical difficulty of depression to zero. The apparent resistance to lowering of the prothrombin time of the plasma below the existing resting level by experimental means should be viewed as a characteristic of this function of the liver. We have observed identical behavior in prothrombin deficiency states also. Thus, in the hypoprothrombinemia accompanying cirrhosis of the liver, serial estimations of prothrombin time have been demonstrated to be remarkably constant within narrow limits over periods of many weeks. Furthermore, when the prothrombin activity was altered by experimental means in these cases, the prothrombin time returned to approximately the initial value when

recovery occurred.⁶ The indications seem to be that the liver delivers its maximum supply of prothrombin under the prevailing conditions, and that when the tempo can be accelerated at all it continues at the new rate for transitory periods only.

It is noteworthy that the changes in the direction of hyperprothrombinemia occurred in only about half of the cases, despite the fact that all exhibited normal resting levels of prothrombin activity. The mechanism suggested is that vitamin K activates a substrate, and that variations in the capacity of different livers to store this substrate might account for the different responses indicated above.

The greater magnitude of the change exhibited by increased dilution of the 8 per cent plasma as compared with 12.5 per cent supports our contention that the shift in the direction of hyperprothrombinemia is functional and not an apparent change produced by mathematical manipulation of the data.

CONCLUSIONS

Reduction of the prothrombin time of diluted (12.5 per cent and 8 per cent) plasma below normal occurred in man with normal liver function following parenteral administration of large doses of menadione derivatives. In each case, where the increase was demonstrable, it continued for transitory periods only, lasting twenty-four to forty-eight hours.*

ACKNOWLEDGEMENTS

This study was aided by a grant from the Blood Transfusion Association of Greater New York. The synkayvite was supplied by Dr. Leo A. Pirk of the Hoffmann-La Roche Company, Nutley, New Jersey. The hykinone was supplied by Dr. Richard K. Richards of Abbott Laboratories, North Chicago, Illinois. The thromoplastin was supplied by Dr. Ralph Overman of the Maltine Company, Brooklyn, New York. Herbert Fensterheim of Washington Square College, New York University, assisted in making the statistical analyses.

A MODIFICATION OF THE WAUGH-RUDDICK TEST FOR INCREASED COAGULABILITY OF THE BLOOD, AND ITS APPLICATION TO THE STUDY OF POSTOPERATIVE CASES

By SEYMOUR B SILVERMAN, M D *

IN 1944, Waugh and Ruddick¹ reported a new test for increased coagulability of the blood, based on controlled deceleration of the clotting mechanism through the use of heparin. While it was appreciated that temperature affected the test, the original work was done at a time when room temperature was constant (i.e., during the winter months), so that special precautions in this direction were unnecessary. Later Whittaker,² working during the summer months, when room temperature fluctuations were present, experienced some difficulty in obtaining duplicate curves, and worked out in detail the facts concerning the effect of temperature on the test. She found that between 20 and 35 degrees Centigrade, increase in temperature caused a decrease in clotting time. This stressed the fact that comparison of the blood coagulation curves in different individuals, or in the same individual at different times, is possible only if the tests are conducted at the same temperature.

Application of the test to clinical material³ revealed an increased coagulability of the blood under a wide variety of circumstances. These include pneumonia, empyema, peritonitis, and other acute infectious processes following hemorrhage after surgical operation, etc. More recently, Ogura and colleagues⁴ have used the Waugh-Ruddick test to study changes in blood coagulation following coronary thrombosis. They found that in 27 cases, 77.8 per cent showed a decreased coagulation time. This was usually evident by the second or third day following the thrombotic incident, and lasted to about the seventeenth day. Acceleration was prolonged beyond the third week in a few cases, but in every instance, the clotting mechanism was indistinguishable from normal after the fourth week.

The present report deals with (1) a proposed modification of the test, and (2) the application of the modified test to the study of postoperative blood coagulability.

A MODIFICATION OF THE WAUGH-RUDDICK TEST

Using the original method of Waugh and Ruddick,¹ blood coagulation studies were carried out on 43 student volunteers. The average curve for this group is shown in figure 1 along with the average curve as determined by the original investigators. It will be seen that although the curves have the same general form, the actual values obtained differ greatly in the two series. There appear to be

two chief reasons for this, viz, (1) the heparin employed was of different batches and thus possibly of somewhat different potencies, and (2) the endpoint in each tube is not sharply defined, and consequently there arises the question of interpretation of results. These and other reasons for modifying the test can be summarized as follows:

1. To shorten the time needed to complete a test

2. To perform the test under controlled temperature conditions

FIG 1. Original Waugh-Ruddick test. Average curves obtained by Waugh and Ruddick, and the author.

FIG 2. Modified Waugh-Ruddick test. Average curve obtained from 36 normal specimens of plasma.

FIGS 3-6. Duplicate curves on normal individuals.

3. To obtain a sharper and more definite endpoint in all tubes

4. To reduce the amount of blood needed to perform the test

Details of the modified test follow:

Solutions Used. (1) Heparin stock solution containing 2 units of heparin per cc of saline. The Connaught Laboratory preparation, having a potency of 1000 units per cc, is employed. Six-tenths of a cc of heparin are added to 300 cc of physiological saline, and thoroughly mixed. This stock solution is used in making up the various subdivisions of heparin, and can be kept in the icebox when not needed.

(2) Subdilutions of heparin are made up as shown in table 1. These are kept in small glass-stoppered bottles with large mouths (capacity 60 cc). The potency of the heparin is maintained by keeping these solutions in a refrigerator.

(3) 0.1 M sodium oxalate: 1.34 Gm. of sodium oxalate are dissolved in 100 cc. of distilled water.

(4) 0.01 M calcium chloride: 0.11 Gm. of anhydrous calcium chloride and 0.42 Gm. of sodium chloride are dissolved in 100 cc. of distilled water.

Preparation of Test Tubes Eight Wassermann tubes (100 x 13 mm.) (previously cleaned in potassium-dichromate-sulphuric acid solution, rinsed out in hot water and distilled water, and dried in an oven) are placed in a suitable rack, and are numbered from 1 to 8. To each tube are added 0.2 cc. of 0.01 M calcium chloride and 0.1 cc. of the heparin subdilution from the correspondingly numbered glass-stoppered bottle. The tubes are corked and set aside.

TABLE 1 — *Preparation of the various subdilutions of heparin, showing the amounts of physiological saline and heparin stock solution used and the resultant heparin concentration in each case*

Bottle	Stock Soln	Saline Soln	Resultant Heparin Concentration
	cc	cc	unit per 0.1 cc
1	0	50	0
2	5	45	1/50
3	10	40	2/50
4	15	35	3/50
5	20	30	4/50
6	25	25	5/50
7	30	20	6/50
8	35	15	7/50

Preparation of Plasma to be Tested By venipuncture, using a dry 20 to 30 cc. graduated Luer syringe and a large gage (No. 18) needle, 4.5 cc. of blood are drawn and mixed immediately and thoroughly with 0.5 cc. of 0.1 M sodium oxalate by repeatedly inverting the stoppered tube. The blood is centrifuged at the rate of 1000 r.p.m. for five minutes, and during this time the rack containing the prepared tubes is placed in a water bath at 37.5 degrees C. This assures the tubes being at body temperature for the test.

After centrifuging for five minutes, the plasma is removed from the packed cells, and 0.1 cc. is added to each of the eight tubes in a water bath. The actual test now begins.

The Test Proper As soon as the plasma has been added to the heparinized tubes, they are agitated slightly to ensure complete mixing of the fluid and the plasma. A stop watch is started when plasma has been added to the last tube.

Starting at about two and a half minutes, the first tube is gently partially withdrawn from the rack, and the plasma is noted for clotting. If this has not occurred, the tube is replaced and examined at half-minute intervals until a complete firm clot has formed. The time is noted. The same procedure is then carried on for tube

2, then tube 3, etc until coagulation has occurred in all tubes The results are plotted on graph paper, the coagulation time against the amount of heparin in each tube

Some Observations Using the Modified Test Tests were done on 36 samples of normal plasma The mean, standard deviation, maximum and minimum values for each tube are given in table 2 The average curve is shown in figure 2 As is to be expected, some individual variation is seen, but this is of the same order as that described in the original Waugh-Ruddick method That the test is reliable in any given case was shown by doing checks on the same plasma samples (figs 3, 4, 5, 6)

Discussion Regarding the Modified Test The modification proposed is in reality a combination of Quick's method of determining the clotting time of recalcified plasma⁵ and the Waugh-Ruddick test¹ As stated by Chargaff, Bancroft and Stanley-Brown, working on methods for the measurement of inhibition of clotting by various substances including heparin, such a method "can only have the accuracy of

the biological test, and not that of a quantitative chemical procedure The chief reason is the fact that the endpoint, namely the formation of a clot, is comparatively ill-defined "6 The average curve (fig. 2) is simply that—an average, and while some tests vary considerably from this, the results obtained in any one case are fairly constant The use of plasma instead of whole blood has rendered the endpoint easier to determine, but other factors equally as important must be taken into consideration As Chargaff⁶ points out, to be successful in studying the action of inhibitors on plasma coagulation the following must be considered

1 The reaction volume must be kept constant, as the numerous substances contained in plasma respond to dilution in different ways The addition, to a series of plasma samples, of increasing amounts of inhibitor solution leads to discordant results

2 Extreme care must be taken to disturb the plasma as little as possible Attempts to increase the precision of the endpoint may adversely affect its accuracy Plasma which coagulates in the presence of an inhibitor in general gives rise to clots that are very soft, and may easily be broken up beyond recognition if shaken before their formation is complete

3 The period of time over which the determination of inhibitor activity takes place should not be too extended, as the clotting properties of plasma may change quite considerably with time

It is felt that the modification outlined fulfills these conditions, and retains the advantages of the Waugh-Ruddick test while avoiding some of the disadvantages

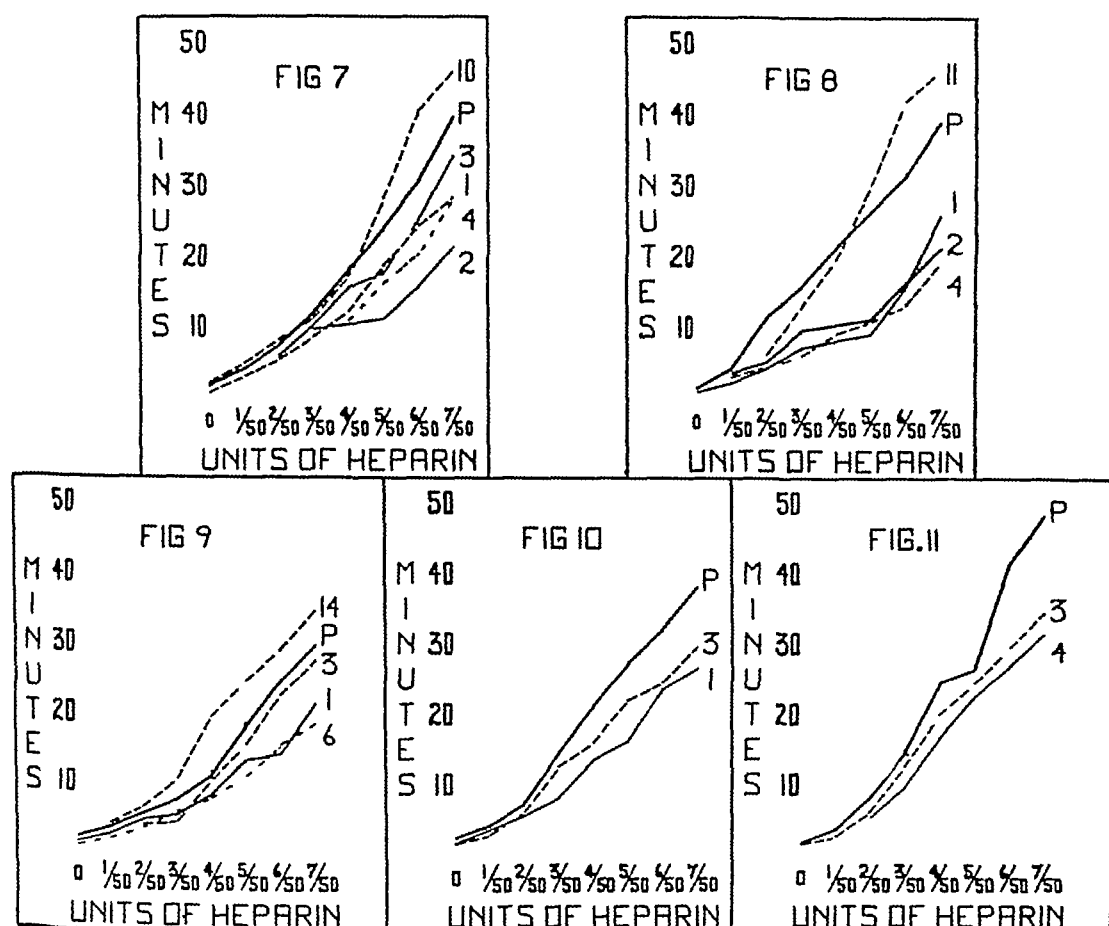

FIG 7 Average curves preoperatively (P), and 1, 2, 3, 4, and 10 days postoperatively

FIG 10 Case 3 Appendectomy The increased coagulability seen postoperatively is indicated by a clockwise shift of the curves

FIG 11 Case 4 Appendectomy Clockwise shift of coagulability curves postoperatively, i.e., increased coagulability

APPLICATION OF THE MODIFIED TEST TO THE STUDY OF POSTOPERATIVE BLOOD COAGULABILITY

Using the above test, it was decided to study the affect of operation on the coagulability of the blood Waugh and Ruddick³ using their test in a wide variety of conditions, applied it to several patients undergoing operation They found a marked increased coagulability after operation, but did not investigate the time

at which it first appeared nor its duration. They state "It would be interesting if finer analysis of this change were studied in order to demonstrate the exact time at which increased coagulability occurs." That is exactly what the present study attempts to accomplish.

In this investigation, tests were performed on 9 patients admitted to the Royal Victoria Hospital for operation. A special effort was made to use patients with no acute illness or any other condition likely to affect the coagulability of the blood. Eight of these were for appendectomy or herniorrhaphy. The ninth was a gastrectomy. All operations were performed under spinal anesthesia. Coagulation tests were done preoperatively and as often postoperatively as possible, commencing the day after operation. The average curves obtained preoperatively and on the first, second, third, fourth, and tenth days postoperatively are shown in figure 7. Some individual records are shown in figures 8-11. In figures 7-9, not all the observed days are recorded, to avoid complicating the graphs. Figures 10 and 11 are complete. Some illustrative cases follow.

Case 1 Mr. P., age 56, admitted for a right inguinal herniorrhaphy. It will be noted that the postoperative coagulability curves are below the preoperative level immediately after operation (i.e., within 24 hours), and for several succeeding days. The coagulation time slowly returns to normal, and is within normal limits by the eleventh day (fig. 8).

Case 2 Mr. C., age 49, admitted for a right inguinal herniorrhaphy. The curves in this case are much like those in case 1. There is a marked increase in blood coagulability postoperatively, with a slow return to normal, in this case by the fourteenth day (fig. 9).

Case 3 Mrs. C., age 37, admitted for appendectomy. The relatively short stay in hospital allowed of only three curves being done. Here again, the increased coagulability postoperatively, indicated by a clockwise shift of the curves, is seen (fig. 10).

Case 4 Mrs. D., age 29, admitted for appendectomy. The story is much the same as in case 3. See figure 11 for coagulability curves.

DISCUSSION

The average curves (fig. 7) indicate that there is a definite increased coagulability of the blood postoperatively. This begins within 24 hours after operation, and may last, in varying degrees, for a week or more. There does not appear to be a definite order in which the coagulability changes from day to day, but this is hardly to be expected, as the test must of necessity be a qualitative rather than a precisely quantitative affair. In all cases where hospitalization was long enough to permit observations, the coagulation time was normal at the end of two weeks.

Quick⁷ points out that "thromboplastin is the trigger-substance in the coagulation process. It initiates and determines the speed of the reaction." If this is so, then the decreased coagulation time seen postoperatively can be explained by an increase in the amount of available thromboplastin. There are two reservoirs of this material, namely the platelets and the tissue juices. Let us consider each of these in turn. Hueck⁸ in 1926 first demonstrated the presence of a postoperative thrombocytosis. This has since been confirmed by many other workers.⁹⁻¹⁶ All agree that this increase in platelets occurs about the sixth or seventh postoperative day. It therefore cannot explain the increased coagulability of the blood seen within 24 hours after operation.

On the other hand, an increase in the circulating thromboplastin, presumably derived from damaged tissue in the operative area, is a much more likely explanation. This view has been favored by Pickering and Mathur,¹⁶ Dougal¹⁷ and others, and is supported by observations that the blood urea and polypeptides are increased postoperatively.¹⁷ Snell¹⁸ and Bancroft¹⁹ point out that after operations on obese patients there may be an increased liberation of thromboplastic lipoid substances such as cephalin, due to extensive areas of fat invaded. Waugh and Ruddick³ showed that the addition of thromboplastin to plasma caused a clockwise shift of the coagulability curves, such as has been shown to occur postoperatively. It would appear that the mechanism is the same in both instances.

SUMMARY

1 A modification of the Waugh-Ruddick test for increased coagulability of the blood is described, which employs the use of recalcified plasma in the place of whole blood.

2 Using this modification, studies were carried out on a series of patients undergoing operation. It was found that there was an increased coagulability of the blood present within 24 hours following operation, and that this condition lasted for a week or so. In all cases, the coagulability had returned to normal by the end of two weeks.

3 It is felt that the change is due to an increase in the circulating thromboplastin, presumably derived from damaged tissue in the operative area.

ACKNOWLEDGMENT

I wish to make grateful acknowledgment to Dr. T. R. Waugh for his advice and assistance during the course of this work and in the preparation of the manuscript.

IN VITRO STUDY OF BONE MARROW III ERYTHROPOIESIS IN VITRO OF STERNAL MARROW FROM CASES OF PERNICIOUS ANEMIA AND LYMPHATIC LEUKOSIS UNDER THERAPY

By JOHANNES CLEMMESSEN, M D , TAGE ESPERSEN, M D , AND
CLAUS MUNK PLUM, PH D

PREVIOUS investigations by one of us (C M P) have demonstrated the possibility of keeping a suspension of bone marrow alive in vitro for several hours for studies on erythropoiesis ³ In the present investigation we have utilized this technic to examine the erythropoietic activity of marrow from normal persons and from cases of pernicious anemia and lymphatic leukosis before and after specific treatment

TECHNIC

The apparatus employed has been described in detail in a previous communication ³ The bone marrow was kept alive between two concentric collodion membranes, and a continuous flow of nutritional fluid was sent through the central chamber, thus permitting a constant composition of the nutritional medium within it, in spite of the diffusion taking place through the membrane out into the suspension of marrow To remove waste products the Locke s fluid in the peripheral chamber was frequently renewed The temperature was kept constant at 37°C by means of a water bath, and a continuous current of carbogen was sent through the chamber

Marrow was obtained by puncture of the sternum and aspiration of 0.5 cc of marrow Sodium citrate 3.5 per cent was added in equal parts, and the cells separated from the fluid by centrifugation With a pipet the intermediary layer of cells was removed for cultivation and brought to a concentration of about 30,000 cells per cu mm in Locke s fluid containing 1 per cent of the corresponding serum The serum to be examined was suspended in Locke s fluid to a concentration of 2 per cent and used as nutritional medium

It was necessary to start cultivation as soon as possible after the sternal puncture, and as no absolute sterility of the apparatus is obtainable the cultivation period was limited to five or six hours

Experiments on leukotic marrow were carried out simultaneously in a set of four parallel apparatus, kept in the same water bath In these cases the first apparatus tested normal marrow against its own serum as nutritional medium, the second chamber contained normal marrow with leukotic serum, the third, leukotic marrow nourished with normal serum, the fourth tested leukotic marrow against its own serum Each experiment thus contained satisfactory controls

The erythropoietic activity was expressed by the number of non-nucleated cells produced during one hour per nucleated red cell present before cultivation The determination of this value may be illustrated by an example from the cultivation of marrow from Case 2

The authors are indebted to Professor C. Sonne, The University Medical Clinic A, Rigshospitalet, Copenhagen, for permission to treat and examine the patients, and to Professor Engelbreth-Holm, The University Institute of Pathological Anatomy, for working facilities during some of the investigations Aided by grants from The Carlsberg Foundation and King Christian the Tenth Fund

NORMAL INDIVIDUALS

It is a weakness of the method that no fixed standard for erythropoietic activity was available. In every case control experiments must be carried out on normal bone marrow planned as the cross experiments to be described. Thus it was im-

TABLE 1—Normal Marrows and Sera Erythropoietic Activities

I	Normal Serum A	Normal Serum B	II	Normal Serum C	Normal Serum D	III	Normal Serum E	Normal Serum F
Normal Marrow A	5 41	4 50	Normal Marrow C	5 17	4 43	Normal Marrow E	4 98	4 18
Normal Marrow B	4 25	5 04	Normal Marrow D	4 51	5 29	Normal Marrow F	4 08	4 85

IV	Normal Serum G	Normal Serum H	V	Normal Serum I	Normal Serum K
Normal-Marrow G	5 09	4 42	Normal Marrow I	4 83	4 05
Normal Marrow H	4 16	4 78	Normal Marrow K	4 15	5 05

portant to know the values for erythropoietic activity of normal marrow. Examinations of marrows from 31 persons were carried out in single experiments with the following results. Average activity was 5.13 ± 0.26 , the maximum value found was 5.88, and the minimum 4.67. Five cross experiments on ten marrows and sera among the 31 are recorded in table 1.

Using the values given above indicating erythropoietic activity we worked out the following ratios for each cross-experiment and the average for all

	I	II	III	IV	V	
1	$\frac{\text{Marrows B, D, F, H, K} + \text{Sera B, D, F, H, K}}{\text{Marrows A, C, E, G, I} + \text{Sera A, C, E, G, I}}$					0.93 1.02 0.97 0.94 1.04 Average 0.98
2	$\frac{\text{Marrows B, D, G, F, K} + \text{Sera A, C, E, G, I}}{\text{Marrows A, C, E, G, I} + \text{Sera A, C, E, G, I}}$					0.79 0.87 0.82 0.82 0.86 0.83
3	$\frac{\text{Marrows A, C, E, G, I} + \text{Sera B, D, F, H, K}}{\text{Marrows A, C, E, G, I} + \text{Sera A, C, E, G, I}}$					0.83 0.86 0.84 0.87 0.84 0.85
4	$\frac{\text{Marrows B, D, F, H, K} + \text{Sera A, C, E, G, I}}{\text{Marrows B, D, F, H, K} + \text{Sera B, D, F, H, K}}$					0.85 0.85 0.84 0.87 0.82 0.85
5	$\frac{\text{Marrow A, C, E, G, I} + \text{Sera B, D, F, H, K}}{\text{Marrows B, D, F, H, K} + \text{Sera B, D, F, H, K}}$					0.89 0.84 0.86 0.92 0.80 0.86

It appears from these figures that as soon as a marrow is nourished on serum from another person erythropoietic activity is reduced to about 85 per cent of the activity between corresponding marrow and serum, but the activity in such a heterologous system is the same whichever marrow-serum combination is employed

In subsequent experiments, similar ratios were set up to calculate the relative effects of normal and pathologic sera upon normal and pathologic marrows. Numbered according to the schema above, these are as follows

		Normal Average
1	$\frac{\text{marrow B} + \text{serum B}}{\text{marrow A} + \text{marrow A}}$	0 98
2	$\frac{\text{marrow B} + \text{serum A}}{\text{marrow A} + \text{serum A}}$	0 83
3	$\frac{\text{marrow A} + \text{serum B}}{\text{marrow A} + \text{serum A}}$	0 85
4	$\frac{\text{marrow B} + \text{serum A}}{\text{marrow B} + \text{marrow A}}$	0 85
5	$\frac{\text{marrow A} + \text{serum B}}{\text{marrow B} + \text{serum B}}$	0 86

The authors realize that computations carried out in accordance with usual conceptions of the validity of standard deviations for countings of cells in fluid media might find our results within the limits of standard deviations. However, after studies by G. Rasch on results obtained by Ruth Plum, it must be accepted that such enumerating can be carried out with far greater accuracy than hitherto assumed.^{3 4} Finally the influence of therapy on our results prevent us from regarding them as merely accidental.

SIMPLE ANEMIA

Cross experiments were carried out in 2 cases of slight anemia

Case A Woman, aged 32. Menses normal, last birth six months earlier. Now tired, irritable and nervous. No abnormal somatic findings, no enlargement of lymph nodes, no goiter. Hb 74 per cent, erythrocytes 4.7 M, color index 0.78. Differential counts of peripheral blood and bone marrow showed normal values.

	Serum Anemic	Serum Normal	Erythropoietic activity on alien serum as per cent of activity on own serum
Anemic Marrow	4 88	4 48	92
Normal Marrow	4 40	5 45	81
			Normal Aver
1	$\frac{\text{Path Marrow} + \text{Path Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0 88	0 98
2	$\frac{\text{Path Marrow} + \text{Norm Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0 82	0 83

		Normal Aver	
3	$\frac{\text{Norm Marrow} + \text{Path Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0 81	0 85
4	$\frac{\text{Path Marrow} + \text{Norm Serum}}{\text{Path Marrow} + \text{Path Serum}}$	0 92	0 85
5	$\frac{\text{Norm Marrow} + \text{Path Serum}}{\text{Path Marrow} + \text{Path Serum}}$	0 90	0 86

Case B Male, aged 28 For the last years very irregular meals Pronounced fatigue and slight dyspepsia combined with headache No pathologic somatic findings Gastric analysis normal Hb 79 per cent, Erythrocytes 4 4 M, Color Index 0 84 Differential count of peripheral blood gave normal values The sternal marrow showed fairly numerous cells of the erythropoietic system (38 per cent)

	Anemic Serum	Normal Serum	Erythropoietic activity on alien serum as per cent of activity on own serum
Anemic Marrow	4 69	4 17	89
Normal Marrow	4 37	5 02	87

		Normal Aver	
1	$\frac{\text{Path Marrow} + \text{Path Serum}}{\text{Normal Marrow} + \text{Norm Serum}}$	0 93	0 98
2	$\frac{\text{Path Marrow} + \text{Norm Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0 83	0 83
3	$\frac{\text{Norm Marrow} + \text{Path Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0 87	0 85
4	$\frac{\text{Path Marrow} + \text{Norm Serum}}{\text{Path Marrow} + \text{Path Serum}}$	0 89	0 85
5	$\frac{\text{Norm Marrow} + \text{Path Serum}}{\text{Path Marrow} + \text{Path Serum}}$	0 94	0 86

Thus, marrows from two cases of simple anemias did not show any pronounced deviation from normal marrows

PERNICIOUS ANEMIA TREATED

Case 1 Woman, aged 44 For about six months, the patient suffered from constipation, increasing fatigue, pains in the tongue and epigastrium Laboratory showed gastric achylia On May 15, 1946 the blood values showed Hb 62 per cent, R B C 2 0 M, color index 1 48, icterus index 7 A differential count of the marrow showed blasts 4 4 per cent, promyelocytes 0 8 per cent, myelocytes 14 4 per cent, metamyelocytes 14 8 per cent, bands 34 per cent, polys 15 2 per cent, monos 0 2 per cent, lymphos 10 2 per cent, plasma cells 0 6 per cent, normoblasts 19 4 per cent, megaloblasts 16 2 per cent

Following treatment with liver extract, within sixteen days the erythrocytes numbered 3 8 million, the hemoglobin was 83 per cent, and the color index was 1 08. The reticulocytes had reached a maximum of 25 7 per cent.

TABLE 2.—*Case 1*

	5/15/46 Pernicious Anemia Serum I (before treatment)	Pernicious anemia		Erythropoietic ac- tivity on alien serum as per cent of activ- ity on own serum
		6/1/46 Serum II (after treat and fall in reticulocyte)	Normal Serum a, b	
Marrow I	2 91		a 4 42	152
Marrow II		4 38	b 5 05	115
Normal Marrow a	3 12		a 4 67	67
Normal Marrow b		4 18	b 5 23	80

Table 2 lists the results of cross experiments using this patient's marrow and various sera

	I	II	Norm Aver
1 $\frac{\text{Path Marrow} + \text{Path Serum}}{\text{Normal Marrow} + \text{Norm Serum}}$	0 62	0 84	0 98
2 $\frac{\text{Path Marrow} + \text{Norm Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0 95	0 96	0 83
3 $\frac{\text{Norm Marrow} + \text{Path Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0 67	0 80	0 85
4 $\frac{\text{Path Marrow} + \text{Norm Serum}}{\text{Path Marrow} + \text{Path Serum}}$	1 52	1 15	0 85
5 $\frac{\text{Norm Marrow} + \text{Path Serum}}{\text{Path Marrow} + \text{Path Serum}}$	1 08	0 95	0 86

Figures 1 and 2 show that the erythropoietic activity of the pathologic marrow when nourished on normal serum not only did not drop by 15 per cent on application of the alien serum but even exceeded normal erythropoiesis by about 50 per cent (Line 4). The pathologic serum, however, failed to keep a normal alien marrow at 85 per cent of its production with its own serum, and reached a level of only about 67 per cent (Line 3). Both these deviations tended to disappear after treatment.

LYMPHATIC LEUKOSIS TREATED WITH URETHANE

Shortly after the publication by Paterson, Haddow, Ap Thomas, and Watkinson on the treatment of leukemia with urethane,¹ we began investigations of the effect of such treatment, both clinically and by means of the technic here described. Technical difficulties prevented corresponding studies on the leukopoietic activity of marrow because of the morphologic similarity of different cells in the early development of the white cell series. Cultivation of marrow was carried out before, during, and after treatment with urethane, which in these cases was supplemented

FIG. 1. Case 2. Leukosis lymphatica

with folic acid, and which gave results in full conformity with those obtained by Paterson and her colleagues.

Case 2 (Figure 1) Woman, aged 66. For a few months, there was increasing loss of strength with expectoration and slight rise of temperature. She was admitted to the hospital, and a diagnosis was made of febrile bronchitis, obesity and osteoarthritis of the knee joints. There was no enlargement of lymph nodes, liver, or spleen. The white cell count was 64,000 with 90 per cent lymphocytes. Sternal marrow showed 70 per cent lymphocytes and the case was diagnosed as lymphatic leukemia. Urethane was given in daily doses of 2 to 4 grams (146 grams in forty days) and was followed by a fall in leukocytes from 60,000 to 70,000 to less than

20,000 in four weeks. After treatment for another two weeks the white cell count was below 10,000. At the beginning of treatment 90 per cent of the white cells were lymphocytes, but ten to eleven weeks later lymphocytes amounted to 25 per cent of the white cells.

At one time folic acid was added to the treatment in the hope of stimulating erythropoiesis, 300 milligrams being given in the course of three days. The fall of the white cell count seemed uninfluenced by this medication. The hemoglobin level was fairly constant at about 80 to 85 per cent.

FIG 2 Case 3 Leukosis lymphatica

Three months after the end of treatment the white count was still normal and the patient was feeling well.

Case 3 (Figure 2) Woman, aged 43. Since adolescence the cervical lymph nodes had been enlarged, varying in size but with no other symptoms. At about 18 she had been treated with roentgen rays, and at 30 by incision of suppurating lymph nodes.

For four years the patient had had increasing loss of strength and weight, progressive enlargement of lymph nodes, sweating, itching of the skin, diarrhea, dry cough, and a tendency to edema of the ankles. Several febrile periods had been

treated as pneumonias In the hospital she was found to have an anemia (Hb 48 per cent), and enlargement of the lymph nodes to the size of an egg, in the neck,

TABLE 3—Case 2

	Serum I, before treatment, 5/31/46	Serum II, during treatment, 6/25/46	Serum III, after treatment, 10/17/46	Normal Serum a, b, c	Erythropoietic activity on alien serum as per cent of activity on own serum

the axillae and the groins The spleen was enlarged 4 to 5 cm below the costal margin The skin of face and neck showed small, firm, pink infiltrations the size of

a pea, which on histologic examination showed leukemic infiltration. Biopsy of a lymph node also showed the histologic picture of lymphatic leukosis.

The white cell count was 72,000, 85 per cent of which were lymphocytes. In the sternal marrow lymphocytes amounted to 80 per cent of the marrow cells. Treatment with urethane in daily doses of 2 to 4 grams (46 grams in fifteen days) caused a fall of the white cell count from 72,000 to about 5,000 in fifteen days. There was a rise in hemoglobin from 48 to 65 per cent. A further increase to 91-98 per cent occurred later. About one month after the end of urethane treatment 300 mg of folic acid were given in the course of five days. At this time there occurred an increase in white cells to over 10,000, but after 3 grams of urethane daily for fourteen days the leukocyte count returned to normal, where it was maintained six weeks later. At this time the lymph nodes had diminished slightly but were still markedly enlarged. The spleen was palpable only during deep inspiration. The subcutaneous infiltrations were uninfluenced by treatment. The patient felt well, and the temperature was normal.

Estimations of the erythropoietic activity *in vitro* of sternal marrow were undertaken in both Cases 2 to 3 both before and after treatment. The points of time are indicated in figures 1 and 2, and the results are tabulated in tables 3 and 4.

The calculated erythropoietic activity under various conditions in relation to the average values observed by cross experiments on ten normal marrows and sera were as follows:

	5/31	6/25	10/17	Normal Average
1 $\frac{\text{Path Marrow} + \text{Path Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0.45	0.82	0.94	0.98
2 $\frac{\text{Path Marrow} + \text{Norm Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0.65	0.96	0.96	0.83
3 $\frac{\text{Norm Marrow} + \text{Path Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0.64	0.87	0.90	0.85
4 $\frac{\text{Path Marrow} + \text{Norm Serum}}{\text{Path Marrow} + \text{Path Serum}}$	1.47	1.17	1.02	0.85
5 $\frac{\text{Norm Marrow} + \text{Path Serum}}{\text{Path Marrow} + \text{Path Serum}}$	1.44	1.05	0.96	0.86
	6/7 I	8/29 II	10/14 III	Normal Average
1 $\frac{\text{Path Marrow} + \text{Path Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0.60	0.75	0.80	0.98
2 $\frac{\text{Path Marrow} + \text{Norm Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0.81	0.95	0.96	0.83
3 $\frac{\text{Norm Marrow} + \text{Path Serum}}{\text{Norm Marrow} + \text{Norm Serum}}$	0.67	0.70	0.85	0.85

		6/7 I	8/29 II	10/14 III	Normal Average
4	<u>Path Marrow + Norm Serum</u>				
	Path Marrow + Path Serum	1 38	1 26	1 20	0 85
5	<u>Norm Marrow + Path Serum</u>				
	Path Marrow + Path Serum	1 12	0 93	1 08	0 86

In both cases, the deviations from the normal values as well as the approach toward the latter after treatment corresponded closely to the findings in pernicious anemia

SUMMARY

Experiments have been performed on sternal marrow kept alive in vitro with serum as a nutritional medium

Cross experiments with marrow and serum from two normal persons show roughly identical values for erythropoiesis. The same applies to marrows and sera from cases of mild simple anemia.

Marrow from a patient with pernicious anemia showed increased erythropoiesis in vitro if nourished on normal serum, whereas serum from the same case lowered the erythropoiesis of normal marrow. After treatment with liver extract, conditions tended to return to normal.

Marrow from 2 cases of lymphatic leukosis displayed corresponding phenomena, and showed a tendency to return to normal after treatment with urethane and folic acid.

Further investigations along these lines are in progress.

STUDIES ON BONE MARROW IN VITRO

III THE EFFECT OF ANOXIA AND HYPEROXIA ON EXPLANTED BONE MARROW

By A. ROSIN, M.D.* AND M. RACHMILEWITZ, M.D.

THE effect of low oxygen tension on hemopoiesis is well known, since numerous observations have been made on men and animals living at high altitudes. It has been established that the increase in red cells and hemoglobin at high altitudes is not due to hemoconcentration or to an abnormal distribution of the blood, but to a real increase in production. The latter is manifested by a rise in reticulocytes in the peripheral blood and by erythroblastic hyperplasia of the bone marrow. These facts led to the widely accepted conception that even under normal circumstances bone marrow activity is largely regulated by the oxygen tension in this organ. Minot and Castle¹ stated that "in the presence of the necessary chemical factors for normal maturation, the supply of red blood cells is regulated largely by the oxygen tension of the bone marrow" (p. 13). It is, however, unknown whether the bone marrow is directly influenced by the fluctuations of the oxygen tension, or whether the response of the bone marrow is provoked indirectly by other factors, initiated by the low oxygen tension, such as the appearance of incompletely oxidized metabolic products, or vasomotor phenomena. It seemed desirable, therefore, to study the direct effect of various oxygen tensions on bone marrow activity. Isolated bone marrow surviving in vitro offered a good opportunity for this purpose.

MATERIAL AND METHODS

The bone marrow from the tibia of 6-8 weeks old rabbits was used. The technic of explantation was that described in the first paper of this series.² The glass tubes containing the bone marrow explants were placed open in a glass flask into which the desired gas mixture was introduced. The gas chamber (diameter 5.5 cm. and height 15 cm.) consisted of two parts, the flask and the cover, connected with a ground glass joint. The flask contained a rack for four culture tubes and a few cc. of water at the bottom to prevent desiccation. After placing the tubes with the cultures in the flask, this was tightly closed with the cover. The cover contained an inlet and an outlet tube of glass, through which the gas was circulated, the inlet tube, reaching the bottom of the flask, the opening of the outlet tube being only a few cm. below the top of the cover. In each experiment two liters of the desired gas mixture were driven through the apparatus and it was then closed by two glass stopcocks in the inlet and outlet tubes.

The gas mixtures were prepared in graduated bottles over water. For mixtures containing less than 20 per cent O_2 , atmospheric air was diluted with nitrogen. For mixtures containing more than 20 per cent oxygen, pure oxygen and nitrogen

From the Department of Experimental Pathology, The Hebrew University and the Medical Department B, Rothschild Hadassah University Hospital, Jerusalem.

* Working under the Cancer Laboratories Fellowship.

were mixed. Oxygen and nitrogen were taken from commercial cylinders, the nitrogen being passed before use over heated copper turnings. The in-going gas was always at atmospheric pressure. The gas chambers thus prepared as well as the control cultures were placed in the incubator at 37°C for 24 hours. Gas mixtures containing 1, 3, 5, 10, 12, 15 and 50 per cent oxygen were used. The control tubes containing atmospheric air were closed with corks as usual.

After incubation the bone marrow explants were fixed together with the plasma clot in Zenker's fluid. Serial sections 4 μ in thickness were cut from the material embedded in calloidin-paraffin. They were stained with hematoxylin-eosin and with Giemsa's stain.

OBSERVATIONS

Cultures of bone marrow incubated in an atmosphere containing 1 per cent oxygen

The cultures maintained in an atmosphere containing 1 per cent oxygen were severely damaged. There were in all 7 cultures treated in this way and all of them presented a uniform picture of disintegration. The stroma appeared brownish in the hematoxylin-eosin preparation, and the stroma cells were mostly damaged. The hemic cells, erythroid as well as myeloid, showed marked signs of degeneration. The nuclei of the erythroblasts and normoblasts showed margination of chromatin or were fragmented, the promyelocytes and myelocytes showed karyolysis. Nuclear debris was scattered throughout the whole preparation. The only cells well preserved were the megakaryocytes. On the periphery of some explants single well preserved polymorphonuclear leucocytes and their precursors could be observed, and very exceptionally a myelocyte was found in mitotic division.

The surrounding plasma contained undamaged polymorphonuclear leucocytes.

Cultures of bone marrow incubated in an atmosphere containing 3 per cent oxygen

Eleven explants were incubated in an atmosphere containing 3 per cent oxygen. Practically all of them showed signs of severe injury of the erythroid and the myeloid cells, similar to those seen in the cultures in 1 per cent oxygen. Here also the megakaryocytes were well preserved. The only difference worth mentioning between the cultures in 1 and 3 per cent oxygen was the presence in some explants maintained in 3 per cent oxygen of a peripheral zone containing a greater number of undamaged cells of all varieties and in all stages of maturation. In this zone mitoses were not rare. In the plasma numerous polymorphonuclear leucocytes were present.

Cultures of bone marrow incubated in an atmosphere containing 5 per cent oxygen

In all 24 cultures were maintained in 5 per cent oxygen. Of these 19 were damaged and the remaining 5 were similar to the controls. The degree of damage was not the same in all injured cultures. Some offered a picture of complete disintegration, others were less uniformly damaged and showed well preserved cells in some peripheral areas of the fragment. In these areas usually the cells of the myeloid series prevailed. The mature leucocytes and erythrocytes were always well preserved.

FIG 1 EXPERIMENT R99 HEMATOXYLIN-EOSIN ($\times 450$)

a) Explant of bone marrow in atmospheric air after 24 hours of incubation

b) Explant of bone marrow in an atmosphere containing 50% oxygen after 24 hours of incubation

Mitoses were present in the less damaged cultures, but their number was always less than in the controls

FIG. 2. EXPERIMENT R92. HEMATOXYLIN EOSIN ($\times 450$)

a) Explant of bone marrow in atmospheric air after 24 hours of incubation

b) Explant of bone marrow in an atmosphere containing 50% oxygen after 24 hours of incubation

Cultures of bone marrow incubated in an atmosphere containing 10 and 12 per cent oxygen

There is no essential difference between the behavior of the bone marrow cultures maintained in an atmosphere of 10 and 12 per cent oxygen, and that of cul-

tures maintained in an atmosphere of 5 per cent oxygen. Out of 28 cultures kept in an atmosphere containing 10 and 12 per cent oxygen, 22 were severely damaged. The remaining 6 were fairly well or well preserved. Here, too, cultures consisting predominantly of erythroid cells were more damaged than those in which the myeloid elements prevailed. The well preserved cultures contained cells in mitotic division, their numbers being, however, less than in the controls.

Cultures of bone marrow incubated in an atmosphere containing 15 per cent oxygen

The cultures maintained in an atmosphere containing 15 per cent oxygen presented quite a different picture as compared with the cultures grown in atmospheres with lower oxygen content. Out of 11 cultures 8 were in good condition and similar to the controls. 3 cultures were somewhat damaged, the normoblasts being here also the most affected. Mitoses in the well preserved cultures were nearly as numerous as in the controls.

TABLE 1 — *Effect of Hyperoxia (50% Oxygen) on the Mitotic Activity of Bone Marrow in Vitro*

Animal No	Percentage mitoses	
	24 hours old explants in atmospheric air 'A'	24 hours old explants in an atmosphere containing 50% oxygen 'B'
R92	3 8	7 8
R93	3 8	6 0
R94	1 4	2 4
R95	3 6	4 8
R96	2 8	7 0
R97	3 8	4 8
R98	2 4	4 2
R99	0 6	2 4

Cultures of bone marrow incubated in an atmosphere containing 50 per cent oxygen

The cultures maintained in an excess of oxygen presented a picture of definitely stimulated bone marrow. They were characterized by their rich cellularity and excellent condition of the individual cells (figs. 1 and 2). In all, 32 cultures were maintained in an atmosphere containing 50 per cent oxygen. Close examination of the cultures maintained at 50 per cent oxygen revealed a distinct feature in their cellular composition, namely the abundance of mature cells, mainly segmented leucocytes. They contained also a varying amount of precursors, predominantly myelocytes, often in mitotic division. The mitotic activity of the cultures was determined by counting the number of mitoses present in 500 cells capable of undergoing mitotic division. The counts made on the experimental cultures and on the controls revealed that the cultures maintained in 50 per cent oxygen contained a higher number of mitoses than the controls (table 1). It thus seems that the higher O_2 -tension had a stimulating effect on multiplication and maturation.

DISCUSSION

No data are available in the literature on the effect of various oxygen tensions on bone marrow cultivated in vitro. The behavior of cultures of other tissues under different oxygen tensions has been the subject of study by a number of investigators.

Burrows³ (1920-22) working with cultures of heart fibroblasts derived from chicken embryos of 4 to 5 days of incubation, found that they could survive and grow temporarily in the absence of oxygen. Fibroblasts of 10 to 15 day old embryos, however, grew only in an atmosphere containing 1.8 and 5.4 per cent oxygen respectively.

Wind⁴ (1926) examined the behavior of Rous sarcoma cultures under entirely anaerobic conditions. He found that in anaerobic conditions the cultures survived and the cells migrated and divided normally for 48 hours. If they were transplanted and cultivated for a further 48 hours under anaerobic conditions, migration occurred, but not as extensively as in the aerobic control cultures. During the third passage the cells in the anaerobic cultures died.

Mottram⁵ (1927) studied the effect of reduced oxygen tension on cultures of rat fibroblasts, kidney and Jensen sarcoma. He found that no cell migration took place in the cultures of fibroblasts and kidney at 40 mm Hg (5.2 per cent O_2) or lower tensions of oxygen. The cultures of Jensen sarcoma were less sensitive to oxygen want, since cell migration could be observed in these cultures even at 20 mm Hg (2.6 per cent O_2). No observations were made as to the occurrence and frequency of cell division in these cultures.

Wright⁶ (1928) determined the critical tension required for cell division in cultures of various tissues. He found that the lowest tension at which cell division takes place was for chicken heart fibroblasts about 12 mm Hg (1.6 per cent O_2), for Jensen rat sarcoma 6 mm Hg (0.8 per cent O_2) and for mouse carcinoma 2146 about 3 mm Hg (0.4 per cent O_2). The condition of the cells was good under tensions of 14.7 mm Hg (1.9 per cent O_2) and above.

Ephrussi, Chevillard, Mayer and Plantefol⁷ (1929), working with cultures of heart fibroblasts of chicken embryos, found that migration took place even in the complete absence of oxygen. However, cell division was inhibited under oxygen tensions of 7 mm Hg (0.9 per cent O_2).

Lippmann⁸ (1933) observed that outgrowth was possible, but at a very reduced rate, in fibroblast cultures under entirely anaerobic conditions. If respiration was reduced to $\frac{1}{2}$, increase of area was diminished to $\frac{1}{2}$.

Julius⁹ (1933) examined cell cultures in gas mixtures containing oxygen from 0 to 96 per cent. He found increase in area even at 1 per cent oxygen. The optimal conditions for growth were seen in an oxygen concentration corresponding to that of atmospheric air. Mitoses were scarce in pure nitrogen.

Gomirato¹⁰ (1934) found inhibition of growth, but no death of cells, in cultures of heart fibroblasts from chicken embryos maintained in pure nitrogen.

Knake¹¹ (1934) is the only author who claimed a growth stimulating effect of reduced oxygen tensions (5 per cent) on fibroblast cultures. In very low oxygen tensions, such as 0.2 per cent, as well as in very high oxygen concentrations, i.e. 100 per cent, the cultures were damaged. Oxygen concentrations of 33 and 66 per cent did not affect the growth of fibroblasts.

The investigations cited above indicate that growth of different tissues in vitro is possible under very low oxygen tensions, and even under anaerobic conditions, but that the growth rate is considerably reduced. The few observations on mitoses in tissue cultures under low oxygen tensions always registered inhibition of mitotic activity. According to Wright mitoses in fibroblasts may be present in oxygen concentrations as low as 1.6 per cent, according to Ephrussi et al. even in concentrations of 0.9 per cent. Growth stimulation of mesenchymal cells, measured by the area of outgrowth, caused by low oxygen tensions, was found only by Knake.

Several authors observed an injurious effect of low oxygen tensions on the cells. Wright found injury of fibroblasts in cultures kept in an atmosphere containing only 1.9 per cent oxygen, and Knake in an atmosphere containing 5 per cent oxygen. It must, however, be kept in mind that these authors studied the outgrowing cells and not the cells in the explant itself, as we did. Our experiments on bone marrow growing in vitro show that the reduction of oxygen concentration below 15 per cent has an unfavorable effect on the marrow parenchyma. This is manifested by

the poor preservation of the explants maintained under low oxygen tensions, and by inhibition of multiplication, whereas cell migration took place under all O_2 -tensions tested. The lower the oxygen tensions under which the cultures were kept the more pronounced was the cell damaging effect and the reduction of mitotic activity. Single cells in mitotic division could be found even in gas mixtures containing 1 per cent oxygen, but the mitotic frequency was greatly decreased under reduced oxygen tensions as compared with the control cultures in air. Our observations indicate that erythroid cells are more sensitive to oxygen want than myeloid cells, hence the particularly poor preservation of cultures derived from predominantly erythropoietic bone marrow.

It is generally accepted that the oxygen physically dissolved in the plasma represents the immediate source of supply to the tissues. The quantity of the physically dissolved oxygen depends on the partial pressure of the oxygen in the atmosphere. Thus plasma saturated with alveolar air, containing 14 per cent oxygen, takes up 0.3 per cent oxygen, plasma saturated with pure oxygen takes up 2.2 per cent oxygen. The oxygen consumed by the tissues is constantly replaced *in vivo* by the oxygen dissociated from oxyhemoglobin. In our *in vitro* experiments the only source of oxygen supply is the respective gas mixture in which the cultures are kept. The volume of the gas mixture is comparatively large in relation to the size of the cultures, so that an ample supply of oxygen is secured during the relatively short period of incubation. It must, however, be kept in mind that the oxygen supply may be different in various layers of the culture, the gas penetrating more readily into the superficial than into the deep layers. This reservation holds true for all the cultures, including the controls in air, and our conclusions are based on the comparison of the conditions of the cultures kept in various oxygen tensions with those of the controls.

The lack of bone marrow stimulation by low oxygen pressure cannot be explained by mere technical shortcomings of our method, especially if a comparison is made between the cultures kept under low oxygen tensions and those under high oxygen tensions, i.e. 50 per cent oxygen, when a distinct stimulation could be seen. The stimulation was shown by an increased rate of multiplication as evidenced by the mitotic count, and by accelerated maturation, especially of the myeloid cells. Thus the cultures maintained at 50 per cent oxygen could be easily recognized by the rich cellularity and by the excellent state of the cells. The stimulated maturation, particularly of the granulocytes, caused by an excess of oxygen, is interesting in view of the frequent finding of leucocytosis in the peripheral blood in animals and men under high oxygen tensions¹²⁻¹⁴. It is not, however, yet established whether this leucocytosis is a real one, or whether it is due to inflammatory changes in the lungs caused by inspiration of air rich in oxygen.

It is obvious that observations made on tissue surviving *in vitro* have only a limited value for the interpretation of processes taking place in the living body. This is also true in the case of anoxia and its effects on blood regeneration. However our findings justify a critical analysis of the widely accepted view that deficient oxygen supply to the bone marrow is the main stimulus for the increased production of red blood cells and hemoglobin.

Paul Bert¹⁴ and Viault¹⁵ were the first to observe increased hemoglobin and red cell formation in men and animals living at high altitudes. Miescher¹⁷ then advocated the view that the physiological regeneration of red cells and hemoglobin was governed by a relative oxygen want existing under normal conditions in the bone marrow. In anoxia bone marrow activity is stimulated to increased blood formation.

Dallwig, Kolls and Loevenhart¹⁸ observed in animals subjected to low oxygen tensions an increase in hemoglobin and a marked extension of the red bone marrow. In accordance with the view of Miescher they came to the conclusion that the bone marrow was stimulated by the low partial pressure of oxygen. The same view was adopted by Schaumann and Rosenquist¹⁹ and by Loewy.²⁰

There are certain facts, however, already pointed out by Miescher,¹⁷ Morawitz²¹ and by Loewy²⁰ which are difficult to fit in with the theory that reduced oxygen tension in the bone marrow itself is responsible for the physiological and the accelerated blood regeneration. If oxygen want is directly responsible for the increased hemopoiesis at high altitudes, one might expect a certain relation between the diminution of the oxygen tension and the degree of blood regeneration. This is, however, not always the case, definite bone marrow stimulation is already found at altitudes of 600-700 meters where a diminished oxygen tension in the tissues can hardly be expected. The increased blood production at altitudes of 2000 to 5000 meters can easily be explained by the reduced oxygen tension, but this increase does not continue at higher altitudes, such as 6000 meters and more, where the proportion of reduced to oxygenated hemoglobin increases rapidly (Hurtado²²).

According to the theory of the stimulating effect of oxygen want, one should assume that strenuous exercise which increases the anoxia, should also augment the blood regeneration. This, however, is not in agreement with the observations of Cohnheim and Kreglinger²³ and Gross and Kestner²⁴ who found that strenuous exercise at an altitude of 10,000 feet produced a fall in hemoglobin.

Furthermore, if oxygen want is the factor responsible for bone marrow stimulation, one should expect that atmospheres rich in oxygen should depress bone marrow activity. Experiments to this effect made on animals reveal contradictory results. Some authors found a decrease,^{25a, 25b} others an increase in red cells.^{12, 26-28} According to Karsner,²⁹ prolonged exposure to high oxygen concentrations produced no changes in the erythrocyte count. In this connection the experiments of Boycott and Oakley³⁰ are significant. These authors failed to find in rats an inhibiting effect of high oxygen concentrations on the regeneration of red blood cells after hemorrhages. The reticulocyte response was rather greater in the rats exposed to 65 per cent oxygen after bleeding and the color index was regularly lower than in the controls.

The definite stimulation of bone marrow activity at high altitudes may be due not to oxygen want in the marrow, but to compensatory factors initiated by the low oxygen tension of the atmosphere. The factors which come into play under low oxygen tension and which may compensate for the oxygen want are increased respiration, increased arterial pressure, increased cardiac rate, and at very high altitudes, increased minute cardiac output. Sands and de Graaf³¹ found in dogs subjected to a reduced oxygen tension in the inspired air an increased systolic discharge, an increased heart rate and a reduced peripheral resistance, all factors leading to an increase of the minute flow of blood through the body. Thus it may

be assumed that in moderate degrees of anoxemia the blood flow may also increase in the bone marrow so that actually there may be no oxygen want, but even a compensating hyperoxemia in this organ

According to Gesell³² a greater utilization of oxygen by the tissues and an actual increase in oxidative energy occurs even during the period of oxygen want, when a normal increase in ventilation is allowed to combat the shortage of oxygen in conjunction with circulatory adjustments. Thus one could assume that a state of "anoxic hyperoxia" might arise in analogy to the "hyperoxic anoxia" postulated by Bean³³ in oxygen poisoning.

The effect on the bone marrow of compensatory processes taking place in anoxic conditions might explain the increased blood regeneration already found in low altitudes, and the fact that at very high altitudes, where the circulatory and respiratory adjustments may become insufficient, no further increase in blood formation occurs.

SUMMARY

The effect of various oxygen tensions on explanted bone marrow fragments was studied. It was found that gas mixtures containing 1, 3, 5, 10 and 12 per cent oxygen have an injurious effect on hemic cells. Bone marrow maintained in these gas mixtures showed various degrees of degeneration, which was the more pronounced the lower the oxygen tension. Mitotic activity was also found to be reduced under the influence of low oxygen tension.

Bone marrow cultures maintained in a gas mixture containing 15 per cent oxygen did not show appreciable changes and were similar to the controls.

Increased rate of maturation and multiplication occurred in bone marrow cultures maintained in an excess of oxygen, i.e. 50 per cent.

The significance of these findings in the light of observations on the effect of anoxia *in vivo* has been discussed, and reported findings on the effect of low oxygen tensions on other tissues *in vitro* have been briefly reviewed.

ELECTRON MICROSCOPE STUDIES OF BLOOD CELLS

By JOHN W. REBUCK, M.D., AND HELEN L. WOODS

IN AN earlier report¹ we have described briefly the technics utilized in the application of the electron microscope to the study of the blood cells and the preliminary results obtained by these technics. They consisted of the study of lymphocytes, macrophages and neutrophilic leukocytes of experimental inflammatory exudates of man as well as the neutrophils, neutrophilic metamyelocytes, lymphocytes and their precursors, red corpuscles and the later stages of normoblasts obtained from the hematopoietic organs of man.

Several excellent, electron micrograph studies of other tissue cells have already been reported, even though the study of these relatively large, thick and more delicate tissue cells with the electron microscope has imposed somewhat greater problems than has the study of bacteria and viruses. Scott and Packer²⁻⁴ reported on the localization of minerals, particularly calcium and magnesium, in striated and smooth muscle,⁵ and Scott and Anderson⁶ studied connective tissue. Schmitt, Hall, and Jakus⁷⁻¹³ have contributed much to our understanding of protoplasmic fibrils in their studies of collagen fibers, protozoan trichocysts, muscle fibers, sperm, flagella, cilia and fibrin. Richards, Anderson and Hance¹⁴ depicted electron micrographs of striated muscle. Clark, Barnes and Baylor¹⁵ and later Buchholz¹⁶ have reported on chromosome structure. Claude and Fullam¹⁷⁻¹⁸ studied isolated mitochondria and sections of guinea pig liver with the electron microscope. Porter, Claude and Fullam¹⁹ devised a method of electron microscopy of tissue cultures of fibroblasts and nerve endings.

A small number of papers have dealt with electron microscope studies of the blood cells or their derivatives. To the best of our knowledge, save for our preliminary report mentioned above, they have concerned themselves with studies of the blood platelets or the mature red blood corpuscles. Wolpers and Ruska²⁰ reported on the structure of the blood platelets and their relation to fibrin. The platelet granulomere was found to consist of from 60 to 120 granules, rarely as few as 20 granules were seen. The hyalomeric protoplasm exhibited a fine framework-like structure (their figure 9). In the course of the clotting process their electron micrographs depict the platelets swelling, aggregation of granules, vacuole and process formation by the hyalomere, loss of all save a remnant of hyalomere, but finally, persistence of the granules as a place of deposition or attachment for the fibrin micelles. In a later paper Ruska and Wolpers²¹ detected regularly spaced, dark cross bands in fibrin fibrils. Wolpers²² separately investigated the structure of the red corpuscular membranes. Electron micrographs of red blood corpuscles and hemolysed erythrocytes are depicted by him. The membranes of the latter were studied after lipid extraction and were composed of an intricate meshwork of long and slender protein fibrils. Barnes, Burton and Scott²³ portrayed in their Fig. 5 a polystyrene-silica replica of red blood corpuscles. Jones²⁴ recently

From the Department of Laboratories, "Henry Ford Hospital, Detroit, Michigan

was able to make methacrylate surface replicas obtaining micrographs of blood cells of a quality similar to those of polystyrene

MATERIALS AND METHODS

We have employed several technics. First, lymphocytes, macrophages and neutrophilic leukocytes of the inflammatory exudate of man were obtained by applying formvar-covered glass cover slips over small lesions produced in the corium of the forearm of human volunteers. To produce these small lesions, the forearm was first cleansed with alcohol, then by means of a sterile scalpel or sterile razor blade, the epithelium was slowly scraped away over a circumscribed area 2 to 3 mm in diameter, until the papillary layer of the corium was exposed. A few minute bleeding points indicate the proper depth. Care must be taken to avoid lacerations or obvious hemorrhage into the bed of the tiny lesion. In keeping with Kolouch's²⁵ investigation of lymphocytic functions in rabbits with the light microscope, a small drop of egg white was next placed on the lesion, to increase the lymphocytic content of the cellular exudate.

A formvar-covered glass cover slip was next placed over the lesion, film side down. The cover slip was then covered with a square of cardboard and the entire preparation was covered with surgical adhesive tape, approximately 2 by 4 inches in size. Additional pressure over the lesion can be obtained by placing a flat-bottomed cork over the adhesive surmounting the cover-slip area, the cork is then held in place by a long narrow adhesive band.

In an hour or two the cells of the inflammatory exudate migrate to the under surface of the formvar film of the cover-slip, spreading themselves out in a thin, single-celled layer. When at definite timed intervals, it is desired to sample the cellular exudate, the film-covered cover-slip is removed from the lesion and the lesion is immediately recovered by a second film-covered glass cover-slip. The cells which migrated to the undersurface of the film-covered cover-slip, while still on the cover-slip, are immediately quick-frozen and dehydrated in vacuo according to Wyckoff's²⁶ modification of the Altmann-Gersh^{27, 28} technic. It should be noted that earlier, Scott and Packer had prepared striated muscle for electron microscopy by plunging the muscle into chilled isopentane before dehydration.

The final specimen mounting is performed as follows. Place the specimen screen over a suitable cell-containing area which has been selected for observation in the electron microscope. The suitability of such areas first may be adjusted roughly by examination under the optical microscope. Next a strip of Scotch tape is affixed over the specimen screen as well as over the entire slide. The Scotch tape is then removed and the film adheres to it. Inasmuch as the specimen screen is interposed between a small portion of the film and the Scotch tape, removal of the specimen screen at this stage will carry along an equal area of the film. The intact cells are thus actually mounted and observed between the specimen screen and the film. This is a direct mounting technic, then, and these specimens are not replicas.

Another satisfactory method of sampling the fresh exudative cells of man was obtained by imbedding a formvar-covered 200 mesh specimen screen, film side down in the lesion instead of surmounting the lesion with the formvar-covered

glass cover-slip The screen is covered as before, the sterile glass cover-slip is also included, this time serving merely as a bland protective surface about the screen For a few hours the diapedesis and extravasations of red corpuscles into the lesion, as well as the cellular debris, will obscure the screens for electron micrographic purposes But if the film-covered screens in the lesion are replaced by means of fine sterile forceps at intervals of several hours, the exudate will gradually thin out and satisfactory preparations can be obtained These formvar-covered specimen screens were prepared in the usual manner as outlined in current texts of electron microscopy

A third technic employed for the study of the blood cells of the lymph nodes, spleen and bone marrow of man consisted of obtaining imprint preparations of portions of such organs upon formvar-covered glass slides Both fresh surgical pathology specimens and specimens obtained at autopsy were utilized The freshly cut surface of a small portion of the organ is very gently brought in contact with a formvar-covered glass slide, without any smearing or pressure The preparations so obtained were also frozen and dehydrated in vacuo The films were then transferred to screens by the modified stripping technic described above in which the cells were again retained intact Rarely in clinical work when more elaborate apparatus was not available, the imprint preparations were merely air-dried

Downey and his associates in this country²⁹⁻³¹ have been persistent advocates of the imprint technic as an adjunct to the detailed cytologic examination of the blood cells with the optical microscope Sweitzer and Winer³² have recently published an illustrated description of this technic for optical examination Once experience has been gained in optical studies by means of the imprint technic, its application to electronic studies is not difficult

RESULTS

Fig 1 is an electron micrograph of a mature red blood corpuscle ($\times 5400$) It is shown merely for purposes of size orientation A micron scale is also shown Such a corpuscle shows no stromal details, but Wolpers²² work on the membranes of hemolysed corpuscles has shown that the surface of the membrane is composed of a fibrous network following the surface curvature Fig 2 ($\times 5400$) is an electron micrograph of an orthochromatic normoblast from a bone marrow imprint The distinct, fine chromatin particles, are partially obscured by denser, coarse chromatin clumps as the red cell undergoes its natural pyknosis The central cell in the next electron micrograph, fig 3, corresponds to the polychromatophilic stage of normoblastic development, this cell was magnified to $\times 5400$ Note the larger areas of finely dispersed chromatin in this nucleus, indicating less nuclear maturity The cytoplasm of both these cells (fig 2 and 3) is scant and not remarkable at this magnification

Fig 4 is an electron micrograph of a small macrophage or histiocyte, obtained from the inflammatory exudate of the arm, magnified to $\times 5400$ This cell measures 9 by 15 microns It was obtained 16 5 hours after inflammation had been produced The horseshoe shaped nucleus, the nuclear-cytoplasmic interface, the cytoplasm and the cytoplasmic surface are plainly seen A portion of the same cell magnified

to $\times 18,000$ in fig 5 shows an interlacing network which goes to form a type of cellular skeleton. The greater portion of fig 5 depicts the delicacy of the nuclear framework. Only the lower central portion of the micrograph contains a small area of the cytoplasmic bay, but it is sufficient to afford ample study of its con-

FIGS 1 TO 4

trasting structure. The nuclear interstices, are, on the average, smaller than those within the cytoplasmic protoplasm, although some of the smaller cytoplasmic spaces measure only 15×30 millimicrons and some of the larger nuclear spaces measure 120×200 millimicrons. The nuclear strands or fibrils appear to be thicker than the corresponding structures in the cytoplasmic protoplasm.

Fig 6 ($\times 21,000$) is an electron micrograph of this cell depicting the major portion of the nuclear indentation and cytoplasmic bay areas. The U-shaped portion of nuclear membrane can be observed as an anchoring membrane for both

FIGS 5 AND 6

cytoplasmic and nuclear structural bands. Fig 7 ($\times 94,000$), is again a micrograph of a portion of this same cell. The upper portion of this figure is cytoplasm, the lower portion nuclear protoplasm. The nuclear membrane runs obliquely across

FIG 7

the lower third of the figure. The individual fibrillar cross-pieces, which can be made out easily in either the nuclear or cytoplasmic protoplasm, actually measure

only 140 to 200 or so Angstrom units in breadth and about 1000 Angstrom units in length

Fig 8 is a micrograph of a second macrophage from the 16 5 hour stage of inflammation in man To the best of our knowledge this is the first electron micrograph depicting phagocytosis Cellular debris has been ingested by a small mononuclear This phagocyte only measures 7×10 microns A delicate rim of cytoplasm is depicted bridging over the particle The vacuolar lining wall is formed by loops of cytoplasmic fibrillae which usually arch out towards the vacuolar lumen and return into the cytoplasm after forming a scallop-like lining for the vacuole Occasionally free ends of these fibrillae appear to project for short distances into the vacuole

Fig 9 ($\times 5400$) is a micrograph of a third macrophage from the eleventh hour of inflammation in another lesion of the forearm Fig 10 ($\times 18,000$) is a high power view of a portion of the nucleus and cytoplasm of the same cell The structural features of the horseshoe shaped nucleus, cytoplasm and nuclear membrane can also be observed in this cell In all of these macrophages at the site of the cytoplasmic surface, the fibrillar structures of the protoplasm seem to project quite freely, without forming a distinct membrane This could be due to slight shrinkage of the cytoplasm with the initial impact of the electrons, if not, the well known sticky character of the surface of such cells may be in some way related to this finding

Fig 11 ($\times 11,000$) is a micrograph of the peripheral portion of the cell body of a fourth macrophage taken from the same lesion as the previous cell at the eleventh hour of inflammation Several linear arrangements of feather-like, clear areas radiate throughout the cytoplasm This finding warrants some discussion of ice crystal artefacts, although, for reasons which will appear below, we do not feel that such spaces represent ice crystal artefacts Simpson³³ analyzed the various factors influencing ice crystal artefacts produced in protoplasm by the Altmann technic Although his work was performed with the light microscope, he found that such artefacts were small enough to disrupt nuclear detail and produce fine reticulation of the cytoplasm in sections of guinea pig liver cells at some distance from the surface of the tissue block The operation of such factors in the production of the extremely small interstitial nuclear and cytoplasmic spaces of our figs 4 to 11 cannot, of course, be definitely excluded at this time Examination of Simpson's fig 3, plate I, reveals, however, that his ice crystal artefacts are many hundreds of times larger than the protoplasmic spaces of our macrophages Kistler's³⁴ concept must also be considered, namely that the water of biological tissues is in the form of small isolated droplets and may undercool without freezing It is probable that the water content of the macrophages is higher than that of the blood cells themselves Certainly it is true that according to Simpson's standards, our preparations approach the optimum as to size of the piece of tissue frozen and ratio of large surface area to small tissue volume It is unlikely that an insulating gaseous phase of any consequence enveloped the cells of our preparations under the conditions of the technic employed Wolpers and Ruska²⁰ demonstrated a type of protoplasmic framework similar to that under discussion, in the hyalomere of blood platelets Their electron micrographs are of platelets not submitted to

freezing of any type Wolpers'²² electron micrograph of an unfrozen red corpuscular membrane likewise shows a type of delicate fibrillar structural framework, dem-

FIGS 8 TO 10

onstrating that the fibrillar structure of protoplasm need not necessarily be a product of ice crystal artefact

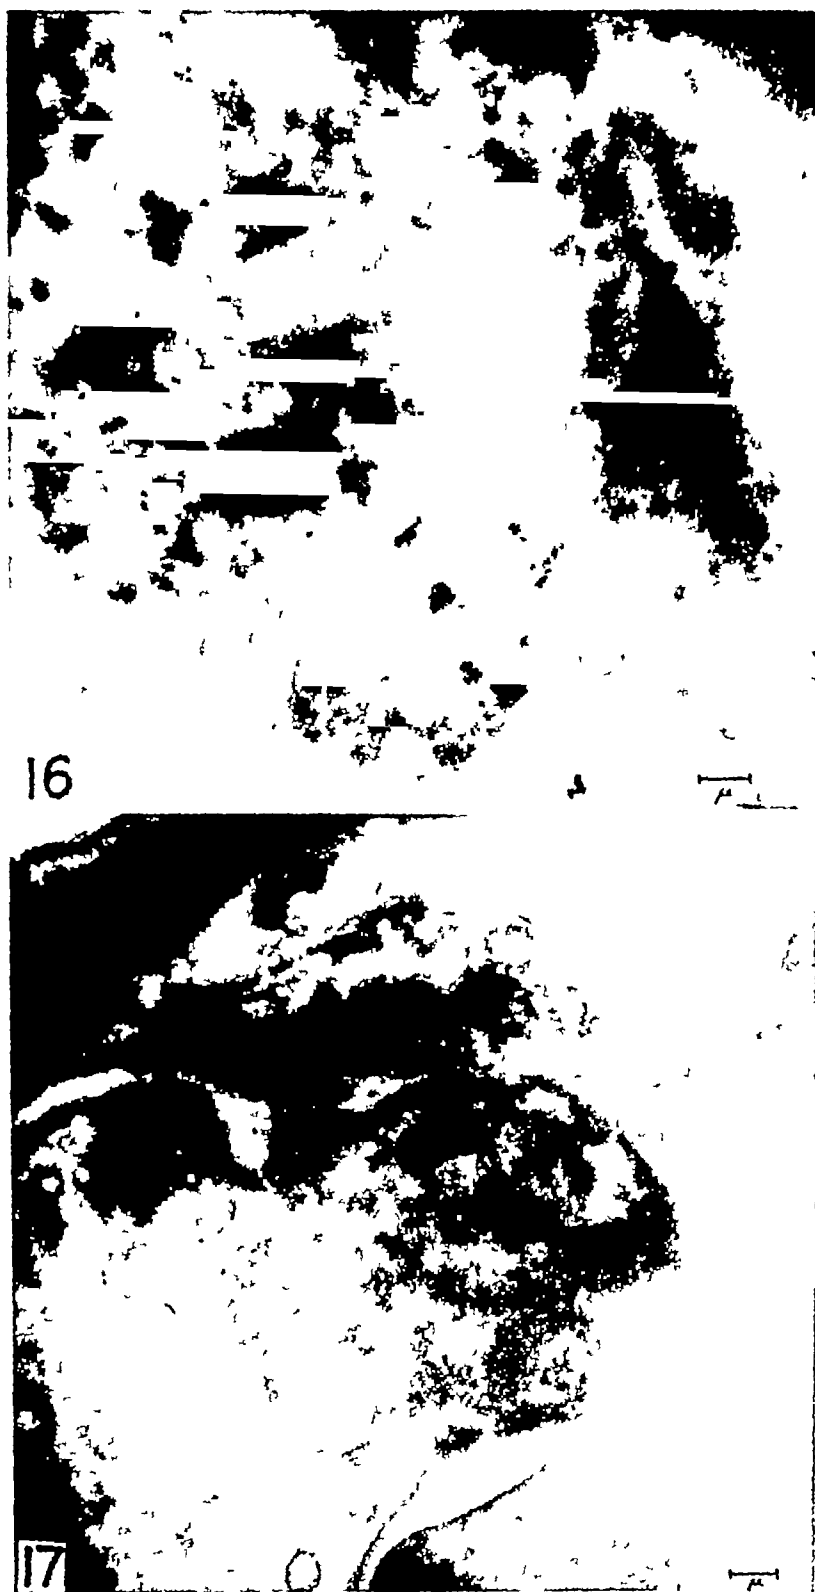

FIGS 11 AND 12

Chambers and Hale,³⁵ on the other hand, employed internal freezing to throw light on structural elements within the cell instead of looking upon it as a possible source of ice crystal artefacts. They demonstrated that the advance of ice columns

FIGS. 13 TO 15

FIGS 16 AND 17

within the protoplasm of frog muscle cells occurred by congealing of the water present in advance of the crystal. Hence it is reasonable to suppose that the steady and uniform advance of the longitudinal ice columns during the internal

freezing of a muscle fibre is along uninterrupted fluid interstices between more solid constituents " To them, the random spreading of fine feathery crystals within the

FIGS 18 TO 20

protoplasm of amoebae indicated a lack of a complicated framework structure. Because of temperature differences between the interior of the cell and its environ-

FIGS 21 TO 23

ment, they assumed the existence of "still finer capillary spaces within the cell." The finding of free fibrillae at the cytoplasmic surface of our macrophages is open to the criticism of their view that to attain internal freezing, the plasma membrane breaks down.

Fig. 12 ($\times 5400$) is a micrograph of one neutrophilic leukocyte and a portion of two others. Neutrophil granules, seen only indistinctly heretofore with the optical microscope, when seen at $\times 18,000$ (fig. 13) are round, oval, or rod-shaped structures. At $\times 47,000$ (fig. 14) and $\times 72,000$ (fig. 15) the neutrophil granules are clearly demarcated. They measure from 70 by 85 millimicrons up to as much as 465 by 650 millimicrons. Figs. 13 and 15 are from the same frozen and dehydrated preparation. Fig. 14 was taken from a preparation which was merely air-dried.

Fig. 16 is an electron micrograph ($\times 5800$) of a neutrophilic metamyelocyte or juvenile from the bone marrow. Its deeply indented nucleus and granular cytoplasm are characteristic features. Fig. 17 is a micrograph ($\times 5400$) of a neutrophilic myelocyte with its round nucleus and the less abundant granular content of its cytoplasm. Fig. 18 ($\times 5400$) is a portion of another neutrophilic myelocyte. Fig. 19 ($\times 5800$) depicts a portion of the nucleus (to the left center) and cell body of an eosinophilic leukocyte. The eosinophil granules are nearly spheres and are quite clear and can be best made out as they overlie the nucleus. Eosinophil granules range from 780×830 up to 1050×1150 millimicrons in size. Fig. 20 ($\times 5800$) represents one of the granulocyte precursors at the promyelocyte or possibly the leukoblast stage. The granules in the cytoplasm are less well-defined, and it is impossible to state whether they represent specific or azurophil granulation. The cytoplasm is more abundant than the preceding stages. The nuclear membrane is exceedingly thin, the chromatin pattern is much finer than the older developmental forms and three or four nucleoli are in evidence. All the developing granulocytes were obtained from bone marrow preparations.

Fig. 21 ($\times 5400$) is a micrograph of a group of three normal, small and medium-sized lymphocytes from a lymph node. This preparation was not frozen or dehydrated, it was merely air-dried. All other preparations with the exception of Fig. 14 were quick-frozen and dehydrated. The coarse chromatin pattern and scant cytoplasm are well shown. Fig. 22 ($\times 5400$) is a micrograph of an extremely immature lymphocyte. The fine chromatin pattern and distinct nucleoli are in sharp contrast to the cells in fig. 21. The immature lymphocyte of fig. 22 was taken from the spleen of a patient with lymphatic leukemia. Fig. 23 ($\times 5400$) depicts a leukemic lymphocyte in amitosis, from a lymph node.

DISCUSSION

Newer concepts concerning the finer structure of protoplasm are just beginning to find their application to the study of the white blood cells. De Bruyn³⁶ has recently interpreted the amoeboid movement of leukocytes in the light of Frey-Wysslings³⁷ structural schemata for protoplasm. The modern concepts³⁷⁻³⁹ of protoplasmic structure comprise molecular configuration of polypeptide chains with their associated intermolecular forces. Between such molecular protein structures are water, salts, mobile protein, and lipid, as well as submicroscopic

particulates which serve in the mediation of special chemical processes. The structural units themselves include at least fibrous and nucleoproteins as well as lipids. The intermolecular forces of structural proteins result in part in their being joined at certain points by chemical bonds. De Bruyn¹⁶ envisions contraction of leukocytic protoplasm as being due to increased binding of such molecular structures at more and more points by chemical bonds, thus narrowing "the meshes of this three-dimensional reticulum," or in keeping with Astbury's¹⁹ findings, as due to actual folding of the polypeptide chains. Solation, then, would involve the loosening of many, but not all, bonds with a resultant loosening of the structural mesh-work, whereas cytoplasmic gelation would mean the locking of more side chains with the structural proteins approaching the formation of a three-dimensional reticulum.

Wolpers'²² micrograph (his fig. 7) of the structure of the nonmotile red blood corpuscle depicts a tightly knit framework suggesting that this may be composed of a mesh-work of long and narrow protein fibrils. The fibrillar structures of platelet hyalomere are not so closely bound as an examination of Wolpers and Ruska's²⁰ micrographs of such structures reveals. We would expect less definite orientation of the structural proteins of the more motile leukocytes and definite orientation in the depolarized derivatives. Menkin⁴⁰ has commented on the fact that macrophages are much more resistant to deformation than polymorphonuclear leukocytes and cites as evidence the fact that rabbit macrophages resist stresses at water-oil interfaces which severely damage polymorphonuclear leukocytes.

The macrophage stage of the various hematogenous and histogenous cellular sources of macrophages is likewise apparently marked by a tendency to sluggish pseudopodial activity. Our micrographs (figs. 4 to 11) of macrophages reveal a complex fibrillar mesh-work with definite structural orientation of both cytoplasm and nucleus. These findings are at least in keeping with modern functional and structural concepts of protoplasm and are suggestive that some of the structural units of protoplasm can be oriented at times to form a framework of linear molecules when the situation requires such reorientation.

SUMMARY

Several technics were employed for the application of the electron microscope to the study of the blood cells. First, lymphocytes, macrophages, and neutrophilic leukocytes of acute inflammatory lesions in man were prepared by imbedding formvar-covered screens in the corium of the forearm. Exudative cells which migrated to the undersurfaces of the specimen screens were quick-frozen and dehydrated in vacuo, according to a modified Altmann-Gersh technic. In some cases formvar-covered glass cover slips were substituted for the screens in the lesions, in which case an extra step was needed to transfer the preparations to specimen screens.

In a further technic, blood cells of lymph nodes, spleen and bone marrow of man were imprinted upon glass slides covered with formvar. These preparations were also frozen and dehydrated in vacuo. The films were then transferred to screens by a direct method in which the cells were retained intact.

Neutrophil granules, seen only as irregular, indistinct granules with the optical

microscope, are actually round, oval, or rod-shaped structures measuring from 70 by 85 millimicrons up to as much as 465 by 650 millimicrons

Immature blood cell precursors were found to possess fine chromatin patterns with distinct chromatin-parachromatin distinction and well-demarcated nucleoli

At the higher magnifications made possible by electron microscopy, a new level of cytostructural organization appeared in the mononuclear phagocytes or macrophages. Individual fibrillar structural units can be made out in both the nuclear and cytoplasmic protoplasm which can be measured in Angstrom units. The nuclear protoplasmic interstices so formed are smaller than the corresponding cytoplasmic areas. The nuclear membrane is actually an anchoring structure for both nuclear and cytoplasmic fibrillar cross-pieces. Phagocytosis is depicted and the wall of the phagocytic vacuole is described. Finally, the observed cyto-structural features of the blood cells are discussed in the light of newer concepts of the finer structure of protoplasm.

CASE REPORT

APLASTIC ANEMIA

SECONDARY TO GOLD THERAPY

By WILLIAM J FITZPATRICK, M D , AND STEVEN O SCHWARTZ, M D

GOLD has become widely used as a therapeutic agent ^{3,7} Its greatest accepted field of effectiveness is in the treatment of rheumatoid arthritis It has also been employed therapeutically for lupus erythematosus and, for many years, especially in France, for all types of tuberculosis Toxic effects are frequent in large series of gold treated cases Hartfall et al ⁷ reported 41.9 per cent incidence of toxic reactions in the treatment of 900 cases Of these reactions 6 per cent were severe, with 7 deaths 3 from hemorrhagic purpura, 1 from agranulocytosis, 2 from liver necrosis, and 1 from exfoliative dermatitis There were adverse hematologic reactions in 10 cases in all In 1942 Cecil et al ³ reported on 245 cases treated with gold Of these, 105 had toxic manifestations (42 per cent) 4 cases were hematologic, and included 3 hemorrhagic purpuras and 1 agranulocytosis A recent report by Lockie et al ⁹ mentions toxic reactions in 20 per cent Whether these toxic manifestations are due directly to the drug or to individual sensitivity is as yet unknown Clinical evidence favors individual sensitivity, since there is often little correlation between the amount administered and the severity of adverse effects Experimental evidence also favors hypersensitivity, ⁸ since toxic symptoms, at least of the hematologic type, could not consistently be reproduced in animals Hematologic manifestations of toxicity, though relatively rare, are among the most serious Of these, thrombocytopenia is the most common with agranulocytosis next in frequency and aplastic anemia the rarest and most serious

Dameshek⁶ reviewed the literature in 1934, and found 6 cases of aplastic anemia due to gold therapy To these he added a case In 1939 Wintrobe et al ¹³ collected 6 more cases and added still another Four more cases have appeared in the literature since that time Giraud⁶ mentioned a case presenting 750,000 red blood cells, 1,800 white blood cells and a granulopenia of 30 per cent following gold therapy Pergola¹⁰ reported the case of a 35 year old dancer who developed aplastic anemia following her second course of gold in which a total of 1 Gm of gold salt was given This case had the classic triad of anemia, granulopenia, and thrombopenia, and in addition a fatty marrow, 80 per cent of whose cells were lymphocytes She recovered after a period of 8 months Armas Cruz and coworkers¹ described a case of aplastic anemia which occurred after a total of only 3 ampules of "Salganol" in-

From the Hematology Laboratory and the Hektoen Institute for Medical Research of the Cook County Hospital, Chicago, Illinois

Aided by a grant from the Wilson Laboratories

intramuscularly and 2 injections of 0.25 and 0.50 gr of gold chloride intravenously. Sternal marrow revealed marked fibrosis. The patient was being treated for lupus erythematosus. Aubert² in 1946 published the case report of a 36 year old female who received a total of 2.1 Gm of "Salganol" and who, 5 months later, developed classic signs and symptoms of aplastic anemia.

Altogether 18 cases of aplastic anemia following gold therapy have been reported, with 4 recoveries. We are describing 2 more cases, both terminating fatally, bringing the total to 20. The cases reported fulfill the diagnostic criteria of gold therapy followed by a syndrome of anemia, leucopenia, granulopenia, thrombocytopenia and hypoplasia or aplasia of the marrow.

CASE REPORTS

Case 1 was a 32 year old white married female who presented herself on July 23, 1946 because of bleeding from the gums, vagina and under the skin for 3 weeks.

At the age of 5 she had had uncomplicated measles and chickenpox. At 12 she began to menstruate, the periods occurring every 21 to 28 days and lasting 2 days. Three years later she had a tonsillectomy which seemed to interrupt a series of moderately severe sore throats. At the age of 20 she had a trichomonas vaginitis and at this time noted that certain areas on her body, especially the arms, were losing their normal pigmentation. This depigmentation was not accompanied by pain, pruritus or local irritation. She married at this time and for the next 4 years tried unsuccessfully to become pregnant. At the age of 25 she began to complain of joint pains. At first the shoulders were involved and after aching for several days the pain passed to the elbows, wrists, knees and small joints of the fingers. These joints subsequently became hot, tender, and swollen. She visited various clinics seeking relief of her joint pains but received little benefit. At about this same time it was found that her uterus was slightly deviated to the left and the right fallopian tube was occluded. By the time she was 27 her joint pains had become more severe, and pain and soreness were present most of the time. She now began to receive shots for her arthritis and after a year seemed to feel much better. At 28 and again at 31 she had exacerbations of her joint symptoms. The shots for the arthritis were discontinued in January 1946. In the fall of 1945 she became aware of the fact that a spot on the top of her head, which had been present for about 8 years and had never bothered her, began to appear inflamed. Her physician prescribed an ointment which had little effect. At the same time she noticed a purplish red rash on both cheeks and the bridge of the nose. However this too had been present, more or less, for 4 years. The rash never caused pain or itching, was always dry, and was darker in color at the time of the menstrual periods. A dermatologist diagnosed the lesion as lupus. She was advised to keep out of the sun and in November 1945 began to receive injections of gold 50 mg per injection every 5 days. These were continued until July 1946, with progressive improvement in the rash.

At the time of her admission to the hospital she stated that she had begun to bleed about 14 days previously. She had no pain but noted that she was weaker than normally and tired more easily. The vaginal bleeding, present for 12 days, and at first consisting only of thin blood, now contained clots. She had been given a shot to stop the vaginal bleeding without effect. One week before admission she developed a fever (which went as high as 102.8°F) and 2 days later her throat became sore. She was given another shot to stop the bleeding and sulfa pills for the sore throat. The sore throat improved but the vaginal bleeding continued, as did the bleeding from the gums. Slight trauma caused the appearance of large black and blue spots on the skin. The only other symptoms of significance were a weight loss of 5 pounds in the preceding 2 weeks and headaches for the preceding 5 days.

On examination she was found to be pale but did not appear seriously ill. There was a nickle sized area of alopecia at the vertex of the skull. The skin was both pigmented and depigmented in various places on both cheeks. Over the bridge of the nose she had a so called butterfly distribution and was more red over the nose than elsewhere. The sclerae were clear, the conjunctivae pale, and funduscopic examination revealed no hemorrhages or abnormal findings. There was a hemorrhagic area on the right buccal mucosa. The gums were soft, friable, and bled upon slight pressure. There were palpable nontender cervical, and

tender submental lymph nodes. The blood pressure was 118/60. The apex of the heart was 8 cm from the mid-sternum in the fifth interspace, and a systolic murmur was heard at the apex and base. There were no palpable organs or masses in the abdomen but there was slight tenderness on deep and superficial palpation in the epigastrium and right lower quadrant. Many bluish ecchymotic areas were seen on all extremities. Many of the small joints of the hands were collared with small hard nodules which seemed to be outgrowths from underlying bone. There were depigmented areas on both arms and legs. The reflexes were normal. Vaginal examination disclosed tenderness in the right cul-de-sac and retroversion of the uterus.

On July 24, 1946 the red cell count was 1.73 million, the hemoglobin 20 per cent (3.1 Gm), and the white cell count was 1,750. There were 2 polys, 95 lymphs, 1 monocyte, 2 eosinophils. Toxicity was 2 plus and poikilocytosis 3 plus. The reticulocyte count was 0.1 per cent and the platelet count was zero. Bleeding time was in excess of 20 minutes while coagulation time was 3 minutes. Total plasma protein was 6.3 grams per 100 cc, carbon dioxide combining power was 29 volumes per cent, chlorides 630 mg of NaCl per 100 cc, and Kahn test was negative. The electrocardiogram showed a sinus tachycardia of 110 with an abnormal, though nondiagnostic, configuration. The urine was alkaline in reaction with a specific gravity of 1.020, 2 plus albumin, 3 plus occult blood, and no sugar, acetone or bile. The marrow obtained from the sternum was, for the most part, replaced by fibrous tissue. Only an occasional normal marrow cell was present. The cellular elements which constituted what remained of the marrow were lymphocytes and plasma cells. The findings were typical of aplastic anemia with fibrosis of the marrow.

The day after admission she was started on 20,000 units of penicillin every 3 hours and the following day she was given 1,000 cc of whole blood. The vaginal bleeding continued and she vomited small amounts of blood. Ten per cent BAL was started in quantities of 2 cc every 4 hours on July 26. In spite of these measures the patient began to bleed profusely from the nose and bilateral nasal packs were required to control the bleeding. Eight cc of 10 per cent BAL was given that day supplemented by 500 cc of blood. The BAL and penicillin were continued, intravenous glucose, saline, and oxygen were given, and alcohol sponge baths and cold enemas were used, but in spite of these measures the temperature rose to 105.6°F 2 days later.

On July 30, 1946 the patient's condition appeared to be terminal. She was dyspneic and extremely weak. Pulse was weak and heart sounds resembled embryocardia. She expired the same day. Permission for postmortem examination was denied.

Case 2 was a 59 year old white married female who, on her first admission to the hospital on May 2, 1944, complained of nose bleeds for 4 weeks and the appearance of black and blue spots for 2 weeks. Her history dated back to 1928 when, at the age of 43, she first began to notice pain and swelling in the joints of the index finger of the right hand. In 1932 she had a tonsillectomy following which the arthritis spread to all the fingers of the right hand and to the toes of the right foot. In 1936 her teeth were removed, but still no relief was obtained from her joint symptoms. By this time the small joints of the left hand were also involved. She continued to have pain interspersed with occasional spontaneous remissions and exacerbations until April 1944. At that time she again presented herself for treatment to her physician. She was given liver, iron, concentrated yellow bone marrow, a bland diet, local heat and injections of gold. The exact dose of the gold is not known but she was given about 8 injections in all.

Her past history revealed no serious illnesses or operations. She had 5 pregnancies of which only 2 were carried to term. As a child she had chickenpox, measles and mumps. Menopause occurred at 41. Menstrual flow was always copious. She could not eat fish, strawberries, cherries or ice cream as these foods caused hives. Her mother and father died of pneumonia, otherwise the family history was non-contributory. She had taken cathartics and Anacin for many years.

The present illness began about 4 weeks before admission to the hospital with the sudden onset of a severe nose bleed, provoked by a rapid change of position from lying to standing. Bleeding continued for several hours and the blood came in gushes. One week later she had a recurrence of bleeding. In both instances the bleeding was principally from the right nostril. About this time she also began to have some dyspnea on exertion and a pounding sensation in her head and ears whenever she changed position rapidly or became excited. These symptoms progressed and 1 week before admission to the hospital she began to have ankle edema which accumulated during the day and disappeared at night. Coincidentally with the onset of the nose bleeds, clusters of small reddish points, principally on her

chest, made their appearance. These spots appeared suddenly and disappeared in about 3 days. At times these spots became confluent. About 2 weeks later, larger purplish black and blue spots began to appear, especially on the upper arms. These were not the results of trauma. Several days later, pain in the right eye, shoulder, hip and thigh appeared. The pain was described as a feeling of soreness, was intermittent in character and at times became severe enough to restrict motion. In addition to the above complaints she noted a gradually increasing fatigueability.

On admission to the hospital on May 2, 1944 she was found to be obese and pale. A small ulcer was seen on the soft palate and another in the right tonsillar fossa. The pharynx was injected. The heart was not enlarged, rhythm was regular, and a soft systolic murmur was heard at the apex. No organs or masses were felt in the abdomen. Multiple petechiae and ecchymoses were seen everywhere on the skin.

Laboratory examination R B C 1,790,000, Hgb 30 per cent, W B C 5,000. Differential 8 polys, 3 eosinophils, 1 basophil, and 88 lymphocytes. The nonprotein nitrogen was 41 mg per cent and the blood sugar was 148 mg per cent. The urine had a specific gravity of 1.014 and was negative for albumin and sugar. The bleeding time was 8 minutes and the coagulation time 4 minutes, 40 seconds. The platelet count by the direct method was 190,000. Stools were negative for occult blood and the Kahn test was negative.

A diagnosis of hypoplasia of the marrow was made. Sternal puncture revealed a moderately cellular marrow. Megakaryocytes were rare. Erythroid development was normoblastic with evidence of great regenerative activity. Granulocyte development was moderately depressed, but adequate numbers of late granulocytes were present to justify the expectation that the granulopenia was a transient phenomenon. Many primitive cells were encountered. The findings were interpreted as compatible with the clinical impression of hypoplasia of the marrow, in a regenerative phase.

She received several transfusions while in the hospital and following her discharge continued to receive about one transfusion every month. In spite of this she persisted in having an anemia, granulopenia and thrombopenia. She began to have rather frequent febrile reactions following transfusions of whole blood and, because of this, red cell transfusions were often given instead.

By the end of 1945, she had received about 18 transfusions, but her condition was essentially unchanged. She was pale and weak and there were pigmented blotches on her zygoma and over the lips. There were bony deformities and partial ankylosis of the distal and interphalangeal joints of the hands. Her R B C was 2,300,000, Hgb 55 per cent, W B C 5,400.

On March 30, 1946 she was again admitted to the hospital for study, complaining of weakness and black and blue spots. By this time she had received 33 transfusions. Physical examination was essentially negative except for obesity, pallor, petechiae, and ecchymoses. Laboratory examination revealed the following: icterus index 6, cholesterol 230 mg per cent with 60 per cent esters, total protein 6 Gm with an albumin of 3.7 Gm and globulin of 2.3 Gm. The fasting blood sugar was 104 mg per cent and the nonprotein nitrogen was 38 mg per cent. Urinalysis revealed nothing except a faint trace of albumin. The stool cultures were negative and the basal metabolic rate was -10. She received 7 blood transfusions and a blood count taken before the last transfusion revealed an R B C of 4,500,000, Hgb 81 per cent, W B C 4,500 with a differential of 30 per cent polys and 61 per cent lymphs. Sternal marrow was now quite cellular but with retarded liberation of mature nucleated red cells and paucity of megakaryocytes. Following this admission she received a therapeutic trial with folic acid (15 mg) and thyroid (130 mg daily).

On September 10, 1946 she was again hospitalized for transfusions, by this time having received 52. Her admission hemogram was R B C 1,940,000, Hgb 38 per cent, W B C 1,500 with a differential of polys 23 per cent, bands 6 per cent, lymphs 54 per cent, monocytes 17 per cent, platelets 30,000.

The patient was last seen on January 17, 1947. Soon afterwards she became ill at home and died suddenly. No postmortem examination was performed.

DISCUSSION

The treatment of toxic reactions secondary to heavy metal therapy had been largely symptomatic until World War II, in spite of the fact that much investigative work was carried out in an attempt to discover effective antidotes for heavy

metal intoxication Following the introduction of BAL (British Anti-Lewisite, 2,3,—dimercaptopropanol) as an antidote for lewisite gas it became effectively used in the treatment of arsenical reactions occurring in the course of antiluetic therapy These results stimulated the investigation of its effectiveness in the treatment of poisoning with other heavy metals and the drug was subsequently found to be similarly effective in counteracting reactions due to mercury, zinc and copper Several publications have appeared of late reporting excellent results with BAL treatment of gold reactions Before administering BAL to man Ragan and Boots¹¹ gave gold and BAL injections to rats to determine if the newly formed compound of BAL plus gold was toxic They were prompted to do this by the report of Waters and Stock¹² that the compound of cadmium and BAL was toxic Ragan and Boots were not able to demonstrate a similar toxicity Of their 5 cases of dermatitis due to gold there was rapid recovery in 4 following the exhibition of BAL It is of interest to note that the urinary excretion of gold was increased following the administration of BAL in all 5 cases The damage in the fifth case was apparently irreversible Cohen et al ⁴ also reported 5 cases of gold toxicity with dermatologic manifestations treated with BAL They felt that the results were good in all cases Lockie et al ⁹ reported 2 cases of hematologic reactions due to gold, one a thrombocytopenic purpura and one a granulocytopenia, in both of which BAL was successfully used

There have been no previous cases of aplastic anemia due to gold reported in which BAL was used The failure of the drug to help in Case 1 above does not imply a condemnation Aplastic anemia in itself has an extremely high mortality Besides this over 25 days had elapsed since the last gold injection had been given and the patient was hardly alive long enough to test the drug's efficacy BAL should certainly be given an adequate therapeutic trial when another case of aplastic anemia due to gold presents itself

SUMMARY

Two cases of aplastic anemia following gold therapy are presented, bringing the total number of reported cases to 20 In one of the cases BAL was unsuccessfully used therapeutically

METHOD

SPINOUS PROCESS PUNCTURE A SIMPLE CLINICAL APPROACH FOR OBTAINING BONE MARROW

By J PHILIP LOGE, M D

ARINKIN¹ in 1929 first described sternal puncture as a practical method for cytologic study of hematopoietic activity and since then this simple procedure has been gaining increasing importance as an aid to the clinician

Other sites for obtaining bone marrow had previously been described Caronia² in 1922 found the aspiration of marrow from the tibia in children to be practical Nordenson³ found it possible to obtain marrow by needle puncture from the head of the tibia and femur, the crest of the ilium, the manubrium or body of the sternum, the ribs and the vertebrae In 2 adults with normal peripheral blood pictures he compared the differential cell counts of marrow from the sternum with that from the vertebrae, ribs, pelvic bone, and tibial epiphyses He found agreement in all but the latter, the tibial epiphyseal marrow proving to be inactive Postmortem examinations of marrow obtained within five hours after death were carried out by Stasney and Higgins⁵ in 14 normal persons following accidental death Differential counts of sternal, vertebral and rib marrow cells agreed satisfactorily

Recently interest has been focused on the iliac crest as a site for marrow aspiration by the work of Rubinstein ^{4*} He studied the results of simultaneous sternal and iliac aspirations in over 200 normal and abnormal individuals, and believes that the procedure of iliac aspiration is simple, that the marrow obtained represents a cytologically active hematopoietic tissue He comments that in diseased states the iliac marrow has at times been much more informative than the sternal marrow

It is the purpose of this paper to describe another site for obtaining marrow by aspiration in adults, namely the lumbar vertebral spinous processes The technic of spinous process puncture is described, and myelograms of marrow collected simultaneously from the sternum and the spinous process are presented for comparison

It is probable that Katsunuma in 1941 (Japan) first used the spinous process puncture as a practical hematologic procedure and it was later adopted by Nakao at the Tokyo Imperial University † In the latter's hands it was preferred to the sternal approach for routine marrow aspirations

From the Division of Hematology, Department of Medicine, Duke University School of Medicine, Durham, North Carolina

* Iliac crest punctures were apparently first described by Van den Berghe of Belgium (Van den Berghe and Blitstein *Presse med*, Aug 4, 1945, p 419) *Editor*

† According to Van den Berghe and Blitstein (*Presse med*, Aug 4, 1945, p 419), A and C Heidenreich (*Prensa Med Argent* 12 2818, 1936) first introduced spinous process puncture, later used more extensively by de Weerdt (*Rev Belge Sc Med* 11 297, 1939) *Editor*

TECHNIC OF SPINOUS PROCESS PUNCTURE

The spinous process of the lumbar vertebrae to be used for marrow aspiration is chosen. We selected L₃ or L₄, depending on which presented the broadest spinous process. If the patient sits up the spinous processes are easily outlined with the fingers. In slender individuals the topographic details can be observed without

FIG 1 KLIMA-SCHLEICHER STERNAL PUNCTURE NEEDLE WITH AN ADJUSTABLE GUARD WHICH ALLOWS PRESSURE TO BE APPLIED NEAR THE NEEDLE POINT

even superficial palpation. An attempt should be made to obtain as much convexity of the lumbar region as possible to make the spinous process more prominent.

The area over the selected site is prepared with a 1-1000 solution of tincture of merthiolate and then infiltrated with a 2 per cent solution of procaine. Then an attempt is made to infiltrate the periosteum over the spinous process.

A Klima-Schleicher sternal puncture needle (fig 1) with the guard set at about $1\frac{1}{2}$ cm is pushed through the skin and fixed with a rotary motion in the spinous process, midway between the upper and lower border. The needle, with firm pressure, is advanced at a 90° angle into the skin until it is firmly fixed to the bone (figs 2 and 3). The obturator is now removed and a dry tight syringe is used to aspirate the marrow. The patient sometimes complains of an uncomfortable sensation as the marrow is being withdrawn. Occasionally at $1\frac{1}{2}$ cm the needle is not firmly fixed, and it is then necessary to reset the guard for a greater depth. This

occurs commonly in patients with heavy musculature or obesity. Rarely, though the needle is firmly fixed, aspiration fails to produce a marrow sample, the needle is then advanced slowly a few millimeters at a time until marrow is obtained. At

FIG. 2. KLIMA-SCHLEICHER NEEDLE FIXED IN THE SPINOUS PROCESS OF THE THIRD LUMBAR VERTEBRA

FIG. 3. LUMBAR VERTEBRAE 2, 3, AND 4 WITH THE KLIMA-SCHLEICHER NEEDLE FIXED IN THE SPINOUS PROCESS OF L₃

no time in our experience was it necessary to go beyond a depth of $2\frac{1}{2}$ centimeters.

Occasionally, some difficulty is encountered when attempting to fix the tip of the needle in the presenting crest of the spinous process. This difficulty is minimized by (1) selecting the spinous process with the broadest surface, and (2) using the Klima-Schleicher needle which makes it possible to apply pressure and direc-

tion near the needle point. In the hands of the author spinous process puncture was not easily accomplished with the Osgood B-D needle or needles of a similar type where no guard is provided near the needle tip.

The marrow cavity of the spinous process is quite limited when compared to that of the sternum. However, an adequate marrow specimen for cytologic study is readily available. There is some variation in the amount of marrow obtainable, depending on several factors: (1) the position of the needle point in the marrow cavity, (2) the size of the anatomic space, and of course (3) the cellularity of the marrow itself. The quantity of marrow aspirated in the series presented here was 0.1 - 0.4 cc, and was easily available in each case.

CLINICAL MATERIAL AND METHODS

Twenty-five patients were selected who were hospitalized for nonspecific upper respiratory infections. Their ages ranged from 17 to 75, 80 per cent of the patients were between 17 and 29.

The spinous process puncture was performed first. Immediately thereafter an equal quantity of marrow was obtained from the sternum opposite the second interspace with an Osgood B-D needle of the same gauge. Following each puncture, cover slip or slide smears were made directly and later stained with either a Wright-Giemsa or Wilson stain. Total nucleated cell counts were done using the unoxalated marrow obtained. Marrow reticulocyte counts, using the brilliant cresyl blue method, were completed in 9 of the 25 cases.

After both spinous and sternal marrow samples had been obtained, a blood sample was drawn by puncturing the finger so that a white blood count, differential cell count, Sahli hemoglobin, and reticulocyte count could be checked. A reticulocyte count was made in 9 of the 25 patients studied.

Hemograms of both sternal and spinous marrow samples were performed (table 1) and 500 nucleated cells were counted in each smear, following the criteria for cytologic identification outlined by Wintrobe.⁶

DISCUSSION

Marrow samples were obtained, in equal quantity, from the spinous processes of L3 and L4 and from the sternum opposite the second interspace. The hemograms, based on 500 nucleated cells, were analyzed and compared favorably. It is true that attempts at accurate quantitative determinations of marrow cellularity have been disappointing, and the procedure of routinely obtaining total nucleated cell counts has been abandoned by some hematologists. Total nucleated cell counts, nevertheless, furnish an estimate of marrow cellularity.

Table 1 lists the essential hematologic data obtained in each case. The differential counts of the peripheral blood samples are not included.

It is important to note that in the two oldest patients, aged 72 and 75, the cellularity of the spinous marrow was equal to that of the sternal sample and that the hemograms were almost identical. This suggests that the marrow of the vertebral spinous processes remains an active hematopoietic center in the advanced age group, an observation, to our knowledge, not previously recorded.

TABLE I — Ten representative paired hemograms of simultaneous marrow samples from the sternum (st) and lumbar spinous process (sp) of L3 or L4 The peripheral blood data is included

The marrow space available for aspiration in any lumbar spinous process is admittedly small. Spinous processes L2, L3, and L4 were obtained from 2 autopsies and subjected to gross examination and some apparent variation was observed in the marrow volume of the vertebral spinous processes of L2, L3, and L4 in the same patient. The variation was greater when the material obtained from the 2 autopsies was compared. Figure 4 shows a median section of L2 from a 75 year old male. Red marrow can be seen in the spinous process and body of the vertebra. No detailed pathologic study was made of the autopsy material as the desired objective was to secure a gross estimate of the size of the available spinous process marrow cavity.

Often, from the technical standpoint, less difficulty was encountered than with the sternal approach. The explanation seems to lie in three factors (1) some pa-

FIG 4 MEDIAN SECTION OF VERTEBRAL BODY AND SPINOUS PROCESS OF L2 FROM A 75 YEAR OLD MALE. RED MARROW IS APPARENT IN THE SPINOUS PROCESS AND BODY OF THE VERTEBRA.

tients complained of less pain during the spinous process puncture, (2) the psychologic value of doing a procedure out of vision of the patient is important, and (3) the avoidance of the disturbing pressure over the less fixed sternum is helpful. A conscientious attempt was made in each case to infiltrate the sternum and spinous process periosteum with procaine. When questioned, 13 patients preferred the spinous approach, 7 the sternal, and 5 gave no choice.

The spinous process puncture is not offered as a method to supplant the sternal route but rather as another technically simple and hematologically reliable way for the clinician to obtain active marrow. The procedure requires no special skill or equipment other than the use of the Klima-Schleicher needle or one of a similar type. When multiple marrow samples are desired the site for puncture can be varied.

It is possible that some patients with a normal cytological sternal marrow pattern may show a pathologic marrow, when such material is obtained from the spinous process

CONCLUSIONS

- 1 The puncture of a vertebral spinous process for the purpose of aspirating bone marrow, is technically a simple procedure
- 2 Hemograms of marrow samples secured simultaneously from the sternum and spinous process of L₃ or L₄ in 25 patients corresponded well
- 3 The cellularity of the spinous process marrow was found to vary insignificantly from that of the sternal marrow
- 4 Spinous process puncture provides the clinician with another approach for obtaining active marrow by aspiration, rivaling the sternal route in simplicity

ACKNOWLEDGMENT

The author wishes to express his appreciation to Mr Edmund E. Malecki for his technical assistance

ADOLFO FERRATA

(1880-1946)

IT IS now a little over a year since Adolfo Ferrata, the great Italian hematologist, died in Pavia where he was Professor of Clinical Medicine. Ideas, methods of research, diagnosis and therapy have changed and progressed enormously from the days when Ferrata started his activity in the field of blood diseases. However, his contributions to the knowledge of blood morphology and

ADOLFO FERRATA

his work as a writer of several textbooks of hematology deserve to be recalled now that he is no longer with us. His reputation was international.

The first hematological work of Ferrata was done after a brief period of activity with J. Morgenroth, under the direction of, and in collaboration with, A. Pappenheim, in Berlin (1910-11). The investigation of the blood cells at that time was strongly influenced by the work of Paul Ehrlich, who had introduced the first staining methods for blood. Pappenheim and Ferrata, opposing the dominant opin-

ions held by Ehrlich, Pinkus, Lazarus, Naegeli, Denys, Levaditi and with minor variations by Grawitz, Weidenreich and Loewit that the "great mononuclear" was the first morphological step in the evolution of the 'polynuclears,' were able to demonstrate that the 'mononuclear cells' of Ehrlich were an independent strain of white cells, and they introduced for these cells the denomination, thereafter universally accepted, of "monocytes" (1910)

The study of the origin of the monocytes led Ferrata to confront the baffling problem of the genesis of white cells in general. In a previous paper he had agreed with Pappenheim on the genesis of the monocytes from the lymphocytes (1910). Soon after, however, Ferrata modified his views, and showed that a nongranulated immature cell, of lymphocytic appearance, may be found in the bone marrow and in the lymph nodes. He believed that this cell was the common progenitor of the red cells, the white granulated cells of the marrow, the monocytes and the lymphocytes. For this stem cell he created the name "hemocytoblast," from then on used by the majority of the hematologists, although not always with the same significance. His hemocytoblast in the marrow is morphologically indistinguishable from that in the lymph nodes, but it is different in its potentiality of maturation into respectively a medullary white cell, a red cell or a lymphocyte. He was thus recognized as a "neounitarian" among the theorists of hematology. The hemocytoblast of Ferrata (1912-1918) is the "free primitive blood cell" of Cunningham, Sabin, and Doan (1925). Although legitimate doubts may be raised as to whether or not hemocytoblasts, morphologically identical to those of the bone marrow (nongranulated myeloblasts), are to be found in the normal lymph nodes of the adult, it is a fact that a differentiation between the stem cells of the medullary elements and those of the lymphocytes is not easy, as everyday experience in the leukemias with highly undifferentiated elements shows. Nowadays clinical hematologists have found an easy but not very scientific way out of these difficulties: they call the immature nongranulated cells 'blasts'.

The progress made in the knowledge of blood morphology and blood genetics could not fail to influence conceptions of blood pathology. Panchromatic staining methods for blood cells had been proposed since the turn of this century (Jenner 1899, Wright 1902, May-Grunwald 1902, Giemsa 1902) and with the aid of this technic it had been almost universally recognized that the cells present in the peripheral blood of leukemic patients were to a far greater extent immature rather than abnormal cells. On the other hand Banti had maintained that leukemias are neoplastic diseases, not fundamentally different from sarcomas and had defended his thesis with anatomopathological evidence in his *Handbook of Pathological Anatomy* (1907) and in a report to the Italian Pathological Society (Pisa 1913). In the discussion which followed this report, Ferrata and Micheli, two young men at that time, rose to oppose the view of Banti, who recognized, at least in part, the validity of their evidence. In the last years of his life Ferrata was no longer so sure of the essential character of leukemias as hyperplastic processes to be differentiated from true neoplastic diseases, and in recent years some of his pupils even advanced doubts about the systematic nature of the various leukemic lesions, un-

earthing ideas stubbornly defended by Banti in the past *Multa renascentur quae jam cecidere*, indeed! All this is good testimonial of the mental alertness, scientific honesty and intellectual elasticity of Ferrata

The name of the Italian hematologist has remained bound to a special type of cell which many authors, after Naegeli, have called the Ferrata cell. According to Ferrata, these elements, which he first saw in leukemic blood (Ferrata and Franco 1919, Ferrata 1924), represent undifferentiated (multipotent) connective tissue cells. Ferrata called them hemohistioblasts, implying that they were cells capable of an evolution into both connective tissue cells and blood cells. Most hematologists share his opinion that connective tissue cells with a capacity for an evolution in both directions really exist. They are the reticulum cells of the blood-forming organs and possibly of other more widely distributed cells (adventitial cells of the blood capillaries, etc.)

The significance of the particular elements described in the peripheral blood by Ferrata under the name of hemohistioblast has been strongly debated and their existence as such even denied by some authors (Ringen, Lambin). The writer showed that cells like those described by Ferrata in leukemic blood are also found in the bone marrow of normal human subjects and of mammals in general (1928). That they are not artifacts, i.e. damaged promyelocytes and myelocytes, as postulated by Ringen and Lambin, is proved by their size (which in many cases is far larger than that of the promyelocytes or myelocytes), their nuclear structure and particularly by the fact that large elements with cytoplasmic pseudopodia, with two blown-up nuclei, with two or three nucleoli, may be seen also in bone marrow sections, often with specific granulations in the cellular body. They represent a form of early differentiation of the reticulum cells into granulocytic elements. This writer, however, has shown that their cellular characteristics are not those of the fixed, pluripotent cells of the connective tissue (reticulum cells), which are the hemohistioblasts in Ferrata's sense. Both in the second edition of his book (1933) and through the work of one of his pupils (Villa 1929), Ferrata accepted this point. Thus it should be recognized that Ferrata not only created an appropriate name expressing a correct idea (hemohistioblast) but that he gave also the first description of a hitherto undescribed type of evolution of the reticulum cell. Similar stages of direct differentiation of the reticulum cells into megaloblasts have also been described by the School of Ferrata in pernicious anemia and acute erythremia (Di Guglielmo).

The contributions of Ferrata are almost totally in the field of morphological hematology. His influence in this direction on a large number of Italian and foreign hematologists, especially those of Spanish and Latin-American origin, was very pronounced. The origin of the blood cells and the relationships between the different cell types were submitted to a minute investigation under experimental conditions, in both normal humans and pathological material by Ferrata and these workers. Cases of blood disease were studied with an almost exclusive interest for the morphology of the blood cells in the peripheral blood, in the bone marrow, etc. Although the achievements in this field were by no means slight, hematology

has a wider scope than pure cytological investigation. And yet Italian hematology has a tradition also of the physiologic approach to the study of blood diseases, from Bizzozzero, Marchiafava, Banti (whose long research on hemolysis is comparatively unknown) down to Zoja, Micheli, Mino, Greppi, Lattes, to name only the better known men. This extreme interest in the morphologic side of blood disorders was very evident in the work of hematologists of many nations at that time. This may have been due to economic limitations which hinder more expensive methods of research. It certainly had a reason in the past. The evidence at hand, however, is to the effect that, although an exact knowledge of blood morphology is a necessary tool for any good hematologist, future progress in the understanding of blood diseases will come from the physiologic approach to these problems.

The activity of Ferrata as a writer of monographs and handbooks started very early with the "Morphology of the Normal and Pathological Blood" (1912). This work was the forerunner of a more extensive handbook "Blood Diseases" (Le Emopatie, 1918-23) which, clearly written and magnificently illustrated with lithographic colored tables (by R. Sarno), had a tremendous success among physicians familiar with the Italian language in Europe and in Latin America. Undoubtedly this book exercised a very great influence in developing interest in hematology in Italy. In the period between the two World Wars, Ferrata in conjunction with several Italian authors (Di Guglielmo, Villa, Introzzi, Greppi, Artom, and others) prepared a new edition in five volumes, which appeared between 1933 and 1935. It is to be regretted that this book is not more widely known. Ferrata contributed a monograph on "The Diseases of the Endocrine Glands" for the Italian "Handbook of Internal Medicine" (Milan 1931), and a "Manual of Blood Diseases," compiled in collaboration with his pupil E. Storti, has just appeared (Milan 1946). This manual is also liberally illustrated with beautiful plates.

Ferrata had a long career as a teacher. In 1922 he was named Professor of Medical Pathology at the University of Messina. He went to Siena in 1923 and the following year he was called to Pavia as Professor of Clinical Medicine. He created a School of Hematology and left behind a distinguished group of scientists, many of them now at the head of several university institutes.

Clear minded and warm hearted, Ferrata was a strong personality and exercised a powerful influence beyond the sphere of his immediate activity. Both in his clinical lectures, as when speaking in medical meetings and congresses, his word was convincing and his intervention clarifying. His powerful physical build, the warmth of his Lombard elocution (he was born in Brescia, a city midway between Milan and Venice), the evident fairness which characterized his approach to any controversy, all contributed to create an atmosphere of sympathetic agreement around him. Although not entirely exempt from the nepotistic habits prevailing in the Italian academic world Ferrata showed himself ready to help young men coming from other schools in the realization of their academic aspirations.

MARROW BIOPSY TECHNIQS

DESCRPTION by Loge in this issue of the spinous process aspiration biopsy of the marrow brings to mind the great development in the use of the marrow puncture as a diagnostic aid in hematologic problems. Although marrow biopsies had previously been occasionally performed, it remained for Seyfarth in 1923 to introduce the sternal approach. The marrow cavity was entered by means of a small trephine and sections of the button of bone, together with curettings, made directly from the marrow cavity were obtained. Arinkin's method of puncturing the sternum by means of a stilletted needle and aspirating a small amount of marrow material proved far more flexible and readily adapted to the clinic. Numerous needles and methods of handling the aspirated material have been recommended, but it is likely that the simplest needle and the least handling give the best results, providing that a small amount of material (no more than 0.5 cc) is aspirated. The sternal puncture has in many respects revolutionized diagnostic hematology, so much so that in many clinics, a case is considered inadequately studied if the marrow puncture has not been performed.

The marrow puncture finds its greatest diagnostic use in conditions of pancytopenia, in splenomegalic disturbances, and in thrombocytopenia. Pancytopenia is more often due to aleukemic leukosis, multiple myeloma, and lymphosarcomatosis than to hypoplasia and aplasia of the marrow. The diagnosis of the leukocytic neoplastic diseases as they invade the marrow is usually readily made by marrow puncture, even when the blood picture is completely noncontributory. This is particularly true of multiple myeloma. In many conditions with splenomegaly, the marrow puncture may be distinctly helpful, as for example, in Gaucher's disease, lymphosarcoma, and the hyperplastic marrow as seen in hypersplenism, etc.

In thrombocytopenic purpura, marrow aspiration is almost obligatory, since in no other way can one be sure that the megakaryocytes are present in normal, increased, or decreased numbers. To remove the spleen when the marrow megakaryocytes are greatly lacking or altogether absent is to invite disaster. Splenectomy should be performed only when it seems reasonably certain that the disorder is idiopathic or hypersplenic and when the megakaryocytes are present at least in normal numbers.

Dry marrow taps are occasionally encountered. This occurs not only with fibrotic marrows but occasionally in the extremely cellular marrows of certain cases of aleukemic leukosis. Under such conditions, it may become necessary to perform a trephine biopsy. In our clinic such necessity occurs very infrequently, perhaps once in fifty punctures. The trephine biopsy gives topographic relationships of marrow to bone, extent of fibrous tissue, etc., but from the standpoint of studying cellular histology, the direct sternal aspiration is unsurpassed. Furthermore, good sections can be made from aspirated material by appropriate fixation.

The need for performing the relatively difficult trephine biopsy has dwindled even more as new avenues for approaching the marrow have been introduced.

Puncture of the iliac crest was introduced a few years ago by Van den Berghe of Belgium and its use emphasized in this country by Rubinstein. Spinous process punctures were apparently first described by A. C. and C. L. Heidenreich in an Argentinian article in 1936, and the Belgian De Weerdts testified as to the good results obtained by this method. The Japanese had evidently been using the spinous process puncture for a number of years before our medical officers in the Pacific learned of it. As stated by Loge, this method has a number of advantages. The patient lies on his abdomen without any exact perception of what is going on, the needle does not go over his "heart," and as a result, there is far less psychic trauma. In addition, the spinous processes are so numerous that serial studies in such conditions as idiopathic thrombocytopenic purpura can readily be made. The method may also be used in infants and very young children, in whom sternal puncture is often quite difficult. The advantage of having at least three sites to puncture has already proved itself in a number of cases in our laboratory. For example, it seemed reasonably certain that a recent patient with splenomegaly, pancytopenia, and a high sedimentation rate had lymphosarcomatosis. Sternal and iliac crest punctures were both extremely hypocellular and unhelpful but the spinous process puncture showed almost a pure culture of lymphoblasts, thus not only making the diagnosis, but foregoing the need for performing a trephine biopsy. Preliminary observations in our laboratory of some 30 comparative sternal, vertebral, and iliac crest punctures indicate that the results are very similar from one site to another and that if there is failure by one method success may be obtained with another.

ERYTHROCYTES AND ERYTHROCYTIC DISEASE

OBSERVATIONS ON THE NORMAL ADULT HUMAN ERYTHROCYTE *P. Ralph* From Department of Anatomy, Ohio State University, Columbus, Ohio *Anat. Rec.* 98: 489-506, 1947

The human red blood corpuscle was studied with bright- and darkfield microscopy in the untreated and treated condition. There is considerable evidence to indicate that there is a plasma membrane, which remains intact even after hemolysis occurs. This membrane contains certain acetone and alcohol extractable lipids which, according to the author, are demonstrable with Sudan black after saturation of the unsaturated bonds. Ralph has confirmed a previous observation (Cowdry, N. H. *Biol. Bull.* 33: 196, 1917) that mitochondria may be present in immature erythrocytes which he has unfortunately referred to as primitive erythrocytes. After cells had been exposed to neutral red for 15-30 minutes, some of them developed refractive globules which were designated as the 'A' granule. The ability of the red blood corpuscle to segregate basic dyes in newly formed vacuoles was first studied by Israel and Papenheim (*Virchows Arch.* 143: 419, 1896) and has been investigated recently by Dustin (*Bull. Acad. Belg. Cl. Sci.* 28: 230, 1942). These, along with reticulation, mitochondria and the vacuole, are signs of immaturity.

O P J

PROLYTIC ION EXCHANGES PRODUCED IN HUMAN RED CELLS BY METHANOL, ETHANOL, GUAIACOL, AND RESORCINOL *E. Ponder* From The Nassau Hospital, Mineola, Long Island, N. Y. *J. Gen. Physiol.* 30: 479-491, 1947

Before red blood corpuscles are hemolyzed there is a loss of potassium with a replacement by sodium derived from the media in which the cells are suspended. When red blood corpuscles were suspended in certain alcoholic solutions it was possible to study large losses of potassium, since the amount of lysis was unusually small. As much as 50 per cent of the potassium may be lost from a cell without greatly affecting the disk-sphere transformation and resistance to osmotic hemolysis.

O P J

OSMOTIC PROPERTIES OF THE ERYTHROCYTE. XII. IONIC AND OSMOTIC EQUILIBRIA WITH A COMPLEX EXTERNAL SOLUTION *M. H. Jacobs and D. R. Stewart* From Department of Physiology, University of Pennsylvania, Philadelphia, and Marine Biological Laboratory, Woods Hole, Mass. *J. Cell & Comp. Physiol.* 30: 79-103, 1947

The problem analyzed and discussed in this paper concerns what happens to the internal composition, the pH, the ionization of hemoglobin, and water content of erythrocytes, if they are placed in a medium containing known quantities of penetrating and nonpenetrating anions, cations, neutral molecules and ionized and nonionized proteins.

O P J

MODIFICATION DE LA RÉSISTANCE OSMOTIQUE DES HÉMATIES PAR QUELQUES CORPS ÉLEVANT LA RÉSISTANCE DES CAPILLAIRES *J. L. Parrot and M. Gabe* *Compt. rend. Soc. de biol.* 141: 363, 1947

The authors study the action of several substances: aesculoside, rutoside, d-epicatechine (which are supposed to possess vitamin P activity) on guinea pigs red cells twice washed with saline. They use a

colorimetric method of measuring the hemolysis and express the results in percentage of the total hemolysis. Rutoside has a very poor solubility in water and it is impossible to obtain a concentration higher than 1.3 per cent. Aesculoside and d-epicatechine are very soluble and higher concentrations were studied. These three substances appear to increase the globular resistance to hypotonic solutions. This action is not stronger with large concentrations than with the very dilute solutions first tested (less than 1.3 per cent for the rutoside). Among the three, the d-epicatechine seems to be the more active as small doses as 2.5 per cent definitely increase the globular resistance. Although the authors do not discuss the specificity of this *in vitro* antihemolytic activity (physical interferences, or pH), these experiments seem worthwhile reporting, any new method of testing the activity of the so-called vitamin P (here, by modifications of the cellular permeability of the red cell) is welcome, since the usual tests for capillary permeability (or resistance) are far from being satisfactory.

NORMAL AND ABNORMAL BLOOD-COUNTS ON THE WITWATERSRAND *G W H Scheepers* From University of the Witwatersrand, Johannesburg, South Africa *J Path & Bact* 59: 199-208, 1947

The three major factors which may contribute to modifying hematologic values on the Witwatersrand are the 6000 foot elevation, the unclouded skies and the general occupation of deep level mining. The results were obtained by examining blood from 100 males and 50 females who were robust and healthy adults, usually between the ages of 20 and 40 years. Medical students were considered unsatisfactory for such studies. There was an erythrocytosis, increased amount of hemoglobin and a slightly elevated color index. Erythrocytes were slightly smaller in diameter and surface area than those from Europeans living at sea level. Leukocyte level was unaltered. Three hundred cases of macrocytic anemia were analyzed statistically. In view of the high normal counts, a large number of patients would be unrelieved of their symptoms if they were not treated before they had fewer than 4.0 million erythrocytes.

O P J

MACROCYTIC HYPERCHROMIC ANAEMIA ON THE WITWATERSRAND *G W H Scheepers* Johannesburg, South Africa *South African Med J* 21: 568-575 and 605-611, 1947

This study deals with the non-mining population, mostly members of Reef Benefit Society Panels, residing on the Witwatersrand in the vicinity of Johannesburg at an elevation of approximately 6,000 feet. From a potential reservoir of 50,000 individuals, 300 persons (0.6 per cent) were found to have abnormalities of the erythrocyte in the direction of macrocytosis and hyperchromatosis. In this area, 6.0 million cells per cu mm and 20.0 grams of hemoglobin per 100 cc of blood are considered average normal values. The mean values for the cases included in the author's series were as follows: erythrocyte count 4.04 million, hemoglobin 18.0 grams, color index 1.37, erythrocyte diameter 7.8 microns, and erythrocyte surface area 102 square microns. The range of the red cell counts in this group was from 1.0 to 7.0 millions. Considerable emphasis is placed upon the hemoglobin surface concentration index which is a measure of the breathing surface of the blood and is calculated by the formula

$$HSCI = \frac{\text{color index}}{\text{mean erythrocyte surface area}} \times 100$$

In the group of cases under consideration, the mean HSCI was 1.06 compared with the normal mean of 1.57, and this is taken as a measure of the lack of physiologic efficiency of the macrocytes. Anisocytosis was regularly present and often marked, while poikilocytosis was less commonly noted (in contrast to pernicious anemia).

Although response to parenteral liver therapy was very good, no conclusions could be drawn as to pathogenesis or epidemiologic factors. The possible roles of constitutional defects, endocrinopathies and urinary infections are discussed. It is suggested that if certain constitutional types fail to achieve adequate adaptation to high altitudes, hypofunction of hemopoietic tissues may be one result.

FAMILIAL HYPOPLASTIC ANEMIA OF CHILDHOOD. REPORT OF EIGHT CASES IN TWO FAMILIES WITH BENEFICIAL EFFECT OF SPLENECTOMY IN ONE CASE *S Estren and W Dameshek* From the Blood Labora

tory of the J H Pratt Diagnostic Hospital and Boston Dispensary, the Boston Floating Hospital, and Tufts College Medical School, Boston, Mass *Am J Dis Child* 73 671-687, 1947

This report is concerned with the first recorded instances in which hypoplasia of the marrow has been noted as the sole familial trait. It is pointed out that the closest similar cases in the literature are those of Fanconi, in which hypoplasia of the marrow was one of a number of congenital and familial abnormalities.

Three of 7 siblings in one family and 5 of 14 in another family had apparently identical disorders characterized by peripheral pancytopenia, pallor, weakness, and bleeding tendency. In the 2 cases in which the marrow was examined, there was quantitative hypoplasia of all elements, but the proportions of erythroid cells were somewhat higher than normal. In one of the cases splenectomy resulted in cessation of the hemorrhagic tendency together with some increase in red cells and leukocytes and a more marked increase in platelets. The spleen was not enlarged and showed no abnormalities.

It is the opinion of the authors that in cases of complete or almost complete aplasia of the marrow, and in cases in which a reduction of platelets is accompanied by a reduction of megakaryocytes in the marrow, splenectomy will probably be of little value. When megakaryocytes are present to some degree in the marrow, however, and particularly when lack of platelet production in the megakaryocytes can be demonstrated, and when, in addition, erythroid elements show some evidence of regenerative activity, splenectomy is deemed worthy of consideration. It is suggested that extirpation of a normal spleen under such circumstances removes the regulatory (inhibitory, humoral) effect on red cells, granulocytes and platelets in the marrow.

The concise review presented of hypoplastic anemias of infancy and childhood is of particular interest because of the confusion created by some of the earlier reports on this subject.

A CASE OF IDIOPATHIC METHAEMOGLOBINAEMIA TREATED BY ASCORBIC ACID AND METHYLENE BLUE *E J King, J C White, and M Gilchrist* From British Postgraduate Medical School, London *J Path & Bact* 59 181-188, 1947

Idiopathic methemoglobinemia was studied in a girl aged 25 years who had had a dusky cyanotic hue of the face, hands, lips, ears and fingernails for as long as she could remember. Total hemoglobin was 17.0 Gm per 100 ml. Oxygen carrying hemoglobin was 10.8 Gm per 100 ml. The 36 per cent difference consisted of 6.2 Gm of methemoglobin. Plasma ascorbic acid concentration was low. The optimum amount of ascorbic acid was between 200 and 300 mg per day. Under such therapy the oxygen capacity of the blood rose and cyanosis lessened in three days and the latter disappeared within a week. Similar results were obtained with methylene blue. When treatment was discontinued there was a gradual return to the previous status. In vitro studies indicate a probable defect in the erythrocyte enzyme system.

O P J

BLOOD CHANGES IN THE AGED *O Olbrich* From the Biochemical Laboratory, Royal Infirmary, Edinburgh, and Queensberry House Hospital, Edinburgh *Edinburgh M J* 54 306-321, 1947

Properly controlled blood studies were made on men and women from 60 to 100 years old. Red cell, hematocrit, mean corpuscular volume, color index and white counts showed completely normal values, with the usual sex difference. These data, in agreement with other reports, indicate the pathologic importance of any degree of anemia in old age.

BLOOD GROUPS, THE Rh FACTOR AND BLOOD TRANSFUSIONS

KERNICTERUS: A FOLLOW-UP STUDY OF THIRTY-FIVE ERYTHROBLASTOTIC INFANTS *R Stiller* From the Children's Hospital, Washington, D C *Am J Dis Child* 73 651-662, 1947

The author points out that with the advent of more detailed knowledge of the pathogenesis and treatment of erythroblastosis fetalis, interest is being focused on possible untoward effects of therapy that may result in a live but helpless infant with kernicterus. Wiener's hypothesis regarding the pathogenesis of kernicterus is cited. According to this concept, agglutinated red cells plug the capillaries of the brain,

causing toxemia. Ganglion cells, being most easily injured by lack of oxygen, die and are then stained by bilirubin.

Follow-up records of 35 cases of erythroblastosis were reviewed. All patients included in the series had had neonatal jaundice or anemia and were Rh positive children born of Rh negative mothers. In the 6 fatal cases no correlation could be shown between severity and extent of clinical manifestations of neurologic involvement and the findings on pathologic examination, only 2 of the 6 showed kernicterus. Of the 29 living children, 4 showed neurologic signs attributed to kernicterus, but in only 2 of these patients was involvement of the central nervous system noted during the neonatal period. These figures are compared with those reported by other observers.

RECHERCHE SUR LA CAUSE DE L'ICTERE GRAVE FAMILIAL DES MULETONS. SES RAPPORTS AVEC LA MALADIE HÉMOLYTIQUE DU NOUVEAU-NE. *J. Caroli et M. Bessis*. Centre National de la Transfusion Sanguine et de Recherches Pématologiques, Paris. *Rev. Hemat.* 2: 207-228, 1947.

There is in the Poitou district of France, a disease, well studied by Sausseau, which affects 8 per cent of new-born mules. It is an acute hemolytic jaundice with hemoglobinuria appearing within a few hours after birth and usually terminating in death. Following the time a mare gave birth to a jaundiced mule, all its offspring will die of icterus gravis. But if this mare is covered by a stallion, the colt will always be healthy. These features, so similar to the hemolytic disease of the human new-born, caught the attention of Caroli and Bessis, and these authors sought for a heteroimmunisation of the mare covered by an ass.

The hematologic examination of the new-born mule with hemolytic jaundice, shows a striking autoagglutination of the red cells, spindle-shaped red cells, microspherocytosis. The anatomic findings are the same as those found in rats treated by hemolytic serum. Dilatation of the hepatic sinus, generalized pigmentar infiltration, but no hydrops foetalis and no kernicterus, as often seen in the human new-born disease. The serologic study shows a very high titer of antibodies against the ass and mule red cells in the serums of the diseased mare, while the other mares have only a few or no antibodies. The antibodies often are incomplete (blocking antibodies). Intravenous injections of an ass blood to the mare increases the titer of the antibodies much more in the immunized mares than in the others.

The authors compare this mule disease to experimental hemolytic jaundice, and to the human hemolytic disease. The mule disease is very close to the experimental disease of the rat and differs from the human disease only by the lack of cytotoxic lesions (cirrhosis, nervous lesions). The parasitic etiology, first considered, is eliminated by these immunologic findings concerning the prophylaxis and therapeutics of the Poitou mule disease, which findings may prove of considerable importance to cattle breeders. The study of this animal disease can also lead to a better understanding of the human hemolytic disease of the new-born.

J P S

THE RH FACTOR. *W. S. Stanbury*. From the Canadian Red Cross Blood Transfusion Service, Toronto, Ontario. *Canad. M. A. J.* 57: 363-370, 1947.

The author presents a well-organized summary of the present status of the Rh-Hr system with particular reference to inheritance and isoimmunization. Readers who are relatively unacquainted with the voluminous and confusing literature in this field will find this review helpful. Some authorities would disagree with the rather firm recommendation that early induction of labor be considered when the mother's serum contains a high titer of blocking antibodies.

L E Y

TRANSFUSIÓN SANGUÍNEA Y TIEMPO DE COAGULACIÓN (BLOOD TRANSFUSION AND COAGULATION TIME). *Alberto S. Benichmol*. *La Prensa Médica Argentina* 34: 3, 154, 1947.

The author reviews the literature favoring direct blood transfusion against the citrated method. Reactions and shock are rare with the former method. He used the metallic apparatus devised by Luis de Marval and the cannula of E. F. Cichetto.

In 20 cases studied, using both the direct and the citrate methods, there were no reactions with the former, and four post-transfusion reactions with the latter. Blood clotting time was definitely

diminished in all cases where the direct method was used, and in only 4 of 10 cases where the citrate method was used

The direct method is, according to the author, the method of choice, whenever blood coagulation time should be shortened preoperatively. It is indicated especially in neurosurgery, in hemophilia, anemias, and hepatic insufficiency

The transfusion should be made twenty-four hours before operation

R M S

LOSS OF VIRULENCE OF *TREPONEMA PALLIDUM* DURING PROCESSING OF DRIED BLOOD SERUM T F Probey

From the Biologics Control Laboratory, National Institute of Health, Bethesda, Maryland. Pub Health Rep 62 1199-1202, 1947

A saline suspension of treponemes of the Nichols strain was prepared from rabbit testicles and mixed with normal horse serum. A portion of the mixture was then used for immediate inoculation into control rabbits and the remainder frozen under vacuum in a bath of carbon dioxide and cellusolve for thirty minutes. Drying of the frozen material was then continued under vacuum for twenty hours with the ampules exposed to room temperature, a procedure which had previously been shown to reduce moisture content to less than 1 per cent. One group of rabbits was inoculated with restored dried material soon after completion of the drying cycle, and a second group was inoculated two days later. Dark-field examination of the resuspended material showed some atypical forms of what appeared to be nonmotile treponemes.

All 3 of the control rabbits developed syphilitic lesions within forty-two days, while none of the 6 rabbits inoculated with processed material developed evidence of syphilis during the observation period of one hundred and forty days. Three successive subtransfers observed for thirteen, seven, and 9 months respectively also remained negative.

These observations confirm the results of Turner, Bauer, and Kluth, and offer somewhat more conclusive evidence that the danger of transmitting syphilis is eliminated by proper freezing and drying of plasma or serum. The author points out that Turner has demonstrated that motility and virulence of *T pallidum* are not altered appreciably by freezing at -78°C and maintenance of this temperature for at least one year. Turner has also showed that freezing at -10° or -20°C does not adversely affect treponemes, but that maintenance at these temperatures for two months causes their death. The practical importance of these studies is obvious.

L E Y

HEMOGLOBINURIA

THE INFLUENCE OF INJECTIONS OF HOMOLOGOUS HEMOGLOBIN ON THE KIDNEYS OF NORMAL AND DEHYDRATED ANIMALS J J Latsch. From the Department of Pathology, University of Wisconsin Medical School, Madison, Wisconsin. J Exper Med 86 153-158, 1947

Hemoglobin solutions containing stroma were injected intraperitoneally in single doses into 37 rats (5 to 7 Gm /Kg) and 26 guinea pigs (1 to 3.5 Gm /Kg) which had been fed and offered water up to the time of injection. Microscopic examination of the kidneys following this procedure revealed an occasional cast in only 2 rats. Sections from the remaining 35 rats and from the 26 guinea pigs showed no casts or tubular changes.

Water was withheld from 16 rabbits for periods of one to five days after which stroma-free hemoglobin solutions were injected intravenously at one time or in divided doses on successive days toward the end of the dehydration period. Water was then withheld for a period of eighteen to 24 hours after the last injection. Thereafter varying amounts of water were given daily for one week. The quantity of hemoglobin injected varied from a single dose of 1.3 Gm /Kg to 1.8 Gm /Kg in eight divided doses on two consecutive days. In the 3 rabbits dying prior to the fourth day following hemoglobin injection, the kidneys were congested and a reddish yellow substance of homogeneous glasslike consistency was observed in the tubular lumina. These collections were not considered to represent formed casts. In 12 of 13 rabbits examined from four to forty days after hemoglobin injection, characteristic pigmented casts and associated tubular dilatation were demonstrated. Minimal necrosis of tubular epithelium in 5 of 13 rabbits was thought to have followed, rather than preceded, the plugging of tubules by casts. Lesions in other organs were of no particular significance.

It is emphasized that consistent reproduction of hemoglobinuric nephrosis has not been previously accomplished without preliminary direct trauma to the kidneys, and that there is need for studying the role of dehydration in other species, particularly man. It should be pointed out that urinary pH was not controlled in this study, and that the hydrated control animals were rats and guinea pigs rather than rabbits.

L E Y

FOLIC ACID

FOLIC ACID Y SubbaRow, R B Angier, et al Ann N Y Acad Sc 48 255-350, 1946

This monograph, comprising a series of thirteen articles by various authors on pteroylglutamic (folic) acid, covers in detail its chemistry, synthesis, pharmacology, physiology, and clinical applications. Published in 1946, it brings together theoretic and clinical investigations available up to the middle of that year. Much of the material has since been recorded in reviews and individual articles elsewhere, especially the description of the synthesis of pteroylglutamic acid and the observations on the patients in the clinic.

It is of interest that the mode of action of folic acid and the absence of marked activity of conjugated forms, are yet controversial. Heinle and Welch (pp 343-346) note the failure of other components of the vitamin B complex, and of biotin, paraaminobenzoic acid, choline, and inositol, to augment the effect of pteroylglutamic acid. The yeast conjugate, they found, was not utilized by human beings, although more recent findings suggest that, in sufficiently large doses, yeast-conjugate is effective (Spies, *Experiments with Folic Acid*, New York, Interscience Publishers 1947, p 101). Nor is conjugated folic acid the extrinsic factor of hematopoiesis. The exact role of folic acid is today, as a year ago, still obscure.

This is a valuable and complete collection of observations on pteroylglutamic acid as of May 1946.
S E

EL EFECTO DE LOS CONJUGADOS DE ACIDO FOLICO EN EL ESPRÚ (THE EFFECT OF FOLIC ACID CONJUGATES IN SPRUE) Ramón M Suárez Bol Asociación Médica de Puerto Rico 39 8 281 1947

In a lecture given at Clínica Pila in Ponce, Puerto Rico, the author gave the results obtained in 4 cases of sprue treated with conjugated forms of folic acid. Fermentation folic acid in daily doses, equivalent to 3.1 mg of folic acid administered intramuscularly, was used in 2 cases, Bc conjugate in daily oral doses of 7 cc, equivalent to 8.4 mg of folic acid, in one case, and another case of sprue was treated with 2 G in daily oral doses of 20 mg.

Both cases treated with fermentation folic acid showed, not only clinical and hematologic improvement, but also an increased urinary output of free folic acid.

The case treated with Bc conjugate showed a striking clinical and hematologic response, but only a slight urinary elimination of free folic acid, and the case treated with 2 G failed to show definite improvement.

As already reported by Suarez, Welch et al, the urinary output of free folic acid increased when concentrated liver extract was added.

It is stated that the mechanism of action of free folic acid, and of its conjugated forms, is unknown, but that it is definitely established that folic acid is not the intrinsic factor of Castle. It may be that folic acid is somehow related to the extrinsic factor, but until more is known about the biochemistry of the antianemic compounds, premature speculations should be avoided.

R M S

OBSERVATIONS ON THE SPECIFICITY OF THE FOLIC ACID MOLECULE T D Spies, R E Stone, and R O Branderburg From the Univ of Cincinnati Studies in Nutrition at the Hillman Hospital, Birmingham, Ala South M J 40 618-19, 1947

The administration of methyl-folic acid to one patient with sprue and one with pernicious anemia was followed by no changes in the peripheral blood, the bone marrow, or the clinical course of the patient. Administration of ordinary folic acid, on the other hand, was followed by a prompt improvement.

The authors argue from this that the particular chemical configuration known as folic acid is highly specific in its effect on erythropoiesis. It would have been of interest to have included sufficient details

concerning the patients to note whether they became worse, since methylfolic acid has actions antagonistic to folic acid, i.e., it is an 'anti-folic acid material' (Arch Biochem 12 318, 1947). Alterations in the glutamic acid portion of the folic acid molecule do not qualitatively affect its activity, since the triglutamyl and heptaglutamyl compounds corresponding to pteroylglutamic acid are both antianemic. Methylfolic acid consists of an alteration in the pteridine portion of the molecule, and antagonizes the action of folic acid. The significance of this chemical alteration, and the uses of antifolic acid compounds, are yet to be determined.

S E

SOME RECENT EXPERIENCES WITH VITAMINS AND VITAMIN DEFICIENCIES *T. D. Spies and R. E. Stone* From the University of Cincinnati Studies in Nutrition, at the Hillman Hospital, Birmingham, Alabama South M J 40 46-55, 1947

During the course of studies on the antianemic activities of pteroylglutamic (folic) acid, a number of related compounds were tested for their possible similar action. Pteroylglutamic acid itself, and pteroyltriglutamic acid (the fermentation factor, also written pteroyl-diglutamyl glutamic acid) were found to have similar actions in pernicious and related anemias. Pteroyl-heptaglutamic acid (also called pteroyl-hexaglutamyl-glutamic acid, the B_6 conjugate material) was also found to give a good response, contradicting in this regard previous findings by Bethell (Univ Mich Hosp Bull 12 42, 1940) and Heinle (Proc Cent Soc Clin Res 19 27, 1946), who had found the heptaglutamic compound to have no effect. According to Spies, this difference is probably a matter of dosage: the body is able to release folic acid from the heptaglutamic compound only in small amounts, but if sufficiently large doses of the compound are given, a good antianemic effect is obtained.

In contrast, there was no antianemic effect from pterotic acid, glutamic acid, or xanthopterin, all chemically related to folic acid.

S E

STUDIES ON THE PATHOLOGIC EFFECTS PRODUCED BY TWO ANALOGUES OF PYRIDOXINE *C. W. Mushett, R. B. Stebbins, and M. N. Barton* From the Merck Institute for Therapeutic Research, Rahway, N. J. Tr N Y Acad Sc 9 291-6, 1947

Materials which are chemically related but physiologically antagonistic to certain substances have recently become important as displacing agents or anti-substances (paraaminobenzoic acid for sulfanilamide, methylfolic acid for folic acid, antivitamin B₆). The present report deals with the changes produced in lymphoid and hematopoietic tissues by two antipyridoxine substances, desoxypyridoxine and methoxypyridoxine.

Interesting findings, produced alike by pyridoxine deficiency and by administration of antipyridoxine compounds, included a reduction in the bulk of the spleen due to hypoplasia of the lymphoid elements. In some species of experimental animals, atrophy of the thymus and the lymph nodes was also present. Concomitant with these abnormalities occurred the development of a microcytic hypochromic anemia, leukopenia, and lymphocytopenia and reduction in the erythroid and myeloid elements of the bone marrow.

An important finding in the adrenal glands consisted of a depletion in the lipid content, with an enlargement of the adrenals. The authors, therefore, speculate—since a relationship between adrenal cortex and lymphopoiesis has been suggested—whether the lymphoid atrophy might be the result of adrenal stimulation rather than the result of a direct action of the antipyridoxines. This question has not yet been answered.

Not all findings were present in all species of animals studied. Variations in species response and doubt as to manner of action make it difficult to attempt to translate these results to human experience.

S E

LEUCOCYTIC DISEASE

THE USE OF BAL (2,3-DIMERCAPTOPROPANOL) IN THE TREATMENT OF AGRANULOCYTOSIS FOLLOWING INTENSIVE ARSENOTHERAPY FOR SYPHILIS *H. L. Hooley* Dept of Medicine, University of Alabama Medical School, Birmingham, Alabama Ann Int Med 27 231-238, 1947

Twelve cases of leukopenia following arsenical therapy are reported. In 7 there was complete absence of polymorphonuclear leucocytes in the peripheral blood and the remainder varied between 5 and 15 per cent. All patients were febrile and 10 showed agranulocytic angina. Treatment consisted of injections of BAL in peanut oil 2.5 mg./kilo every four hours for the first two days, then 1-2 times a day for six days. Penicillin and sulfonamide drugs were not employed. Recovery occurred in all cases and provides further convincing evidence of the effectiveness of BAL in counteracting toxic manifestations of arsenic and other heavy metals.

UN NOUVEAU CAS D'ADÉNO-LYMPHOÏDITE AIGUË BÉNIGNE À DÉBUT INGUINAL AVEC ULCÉRATION GÉNITALE (A NEW CASE OF BENIGN ACUTE LYMPHADENITIS BEGINNING IN THE INGUINAL REGION WITH GENITAL ULCERATION) R. Demanche and P. Lersb. Sang 18 93, 1947

This is the third case published in France of infectious mononucleosis with a genital ulceration and inguinal adenopathy (the others published by P. Chevallier and by Chassagne & Forgeois). The patient, 23 years old, noticed on the first of May a slight genital erosion on the penis, the tenth of May an inguinal adenopathy appeared. The patient was seen for the first time on the sixteenth of May. He was tired, with 38.8°C fever. The genital ulceration had disappeared, but several lymph nodes formed in the left groin. The twenty-eighth of May, the adenopathies were generalized, especially in the cervical area. The volume of the spleen was increased. On the second of June the fever receded. The hematologic examination (twenty-fourth of May) gave the following results: leucocytes, 7400, polynuclears, 35, lymphocytes, 43, monocytes, 23. On the thirtieth of May a Paul and Bunnell reaction was strongly positive serum alone, 2 222 222 210, serum + guinea pig kidney, 2 222 222 210, serum + beef red cells 0 000 000 000. On the twenty-second of June, the mononucleosis predominated in the blood, the Paul and Bunnell also was still slightly positive. How should one interpret this genital ulceration? Since it was the first symptom and a transitory one it cannot be a trophic ulceration due to the hypogranulocytosis. Was it the point of entrance of the unknown virus of the disease? Another venereal contamination is possible, but there was no reason to suspect it and the wife of the patient remained healthy.

INFLUENCE OF OESTRONE ON THE LYMPHOID TISSUES OF MALE MICE. L. Dmochowski and E. S. Horning. From Laboratories of the Imperial Cancer Research Fund, Mill Hill, London. J. Path. & Bact. 59 307-312, 1947

The reported higher incidence of tumors in female mice led the present authors to investigate the association of oestrogenic stimulation and neoplasms in male castrate mice. Two strains of male mice were used in 3 groups from each. Group 1 was castrated and then painted with oestrone. Group 2 was painted but not castrated. Group 3 was the control group. The incidence of lymphoid tissue changes in both test groups was much higher than in the control and higher in the castrate than non-castrate. It has not been determined whether or not these lymphoid changes were of a truly malignant nature.

LYMPHOMA AND BONE TUMORS

LE TRAITEMENT CHIRURGICAL DE LA MALADIE DE HODGKIN (SURGICAL TREATMENT OF HODGKIN'S DISEASE) Jean Bernard. Paris. Bull. et mém. Soc. méd. d'Hôp. de Paris. 4^e série, 63^e année, nos 23, 24, et 25 613-616, 1947

Jean Bernard, author with P. Chevallier of an excellent monograph on Hodgkin's disease, reports the results of surgical attempts to treat Hodgkin's disease.

In 6 children, a cervical lymph node which was hypertrophic was removed. In these cases, there were no other adenopathies, and the mediastinum and the spleen were not involved. There was no fever. The diagnosis of Hodgkin's disease was made on histologic examination. Tuberculin reactions were negative, and then there were only slight modifications of the white cell counts (neutrophilia and slight eosinophilia).

Two of the 6 children, are still alive and in perfect health, 6 and 8 years after the operation. In the other 4 cases the disease progressed as if no surgical attempt had been made. After 3 to 12 months new adenopathies appeared. The surgical procedure was excision of the hypertrophic lymph node, without

"evidemment ganglionnaire" At this initial period, the clinical diagnosis of Hodgkin's disease is only presumptive before histologic examination. The unnecessary removal of an inflammatory lymph node is preferable to losing precious time awaiting a more characteristic picture.

These observations have a theoretic interest. Hodgkin's disease seems to have a short, localized, initial stage, even if it is a system disease (as the fowl-leucosis has a first, medullary, localized stage). The practical interest is considerable. Since the surgical removal has no detrimental effects on the course of the disease, two successful results in six attempts bring hope in the treatment of this fatal disease.

TUMORS OF THE SKELETAL SYSTEM. MEDICAL ASPECTS. *A. B. Gutman*. From the Department of Medicine, Columbia University College of Physicians and Surgeons and the Presbyterian Hospital, New York, N. Y. *Bull. New York Acad. Med.* 23: 512-518, 1947.

The clinical hematologist who is often called upon to assist in the differential diagnosis of bone tumors will find much of interest in this straightforward presentation. The significance of abnormal blood levels of calcium, inorganic phosphate, alkaline phosphatase, acid phosphatase and serum proteins is given in tabular form and briefly explained. Recent advances in medical treatment of bone tumors are cited as examples of current trends but are not discussed.

L E Y

TUMORS OF THE SKELETAL SYSTEM. PATHOLOGICAL ASPECTS. *H. L. Jaffe*. From the Hospital for Joint Diseases, New York, N. Y. *Bull. New York Acad. Med.* 23: 497-511, 1947.

This concise presentation, like the above, merits attention from those interested in the blood and blood-forming organs. The pathologic and some of the clinical features of the most important bone tumors are clearly described. The author recognizes two general cytologic groups of multiple myeloma, namely, the plasma cell myeloma or plasmacytoma, and a group of more varied cytology dominated by cells larger than plasma cells. The pathognomonic findings in the kidneys in this disease and the presence of amyloid in some cases are stressed. With regard to roentgenographic evidence of multiple myeloma, it is emphasized that when films of the other bones do not show the conventional picture, the calvarium as a rule also fails to show it.

L E Y

LYMPHOMATOUS DISEASE

MALIGNANT LYMPHOMA. THE VALUE OF RADICAL SURGERY IN SELECTED CASES. *C. A. Hellwig*. From the Department of Pathology, St. Francis Hospital, Wichita, Kansas. *Surg. Gynec. & Obst.* 84: 950-958, 1947.

An analysis of the clinical and pathological features of 130 cases of malignant lymphoma is presented. A close correlation existed between the histology of the tumor and the life expectancy of the patient. Sixty-seven cases were subjected to radical surgery and 63 of these survived the operation. Twenty-one of these patients received no other form of therapy and 12 of these survived 5 years or longer, and showed no evidence of disease at the time of the report.

Forty cases received adequate radiation therapy following radical removal of the tumor. Eighteen of these patients survived and 9 were without evidence of disease at the time of the report.

From reports such as this it is apparent that radical excision of localized accessible lymphomatous tumors should be attempted. Hellwig stresses the fact that radiation therapy alone does not produce cure of malignant lymphomatous disease and actually prolongs the life of its victims very little. In contrast, radical excision of the tumor may occasionally result in complete cure, and frequently prolongs life.

J F R

ASPIRATION BIOPSY OF LYMPH NODES. A CRITICAL REVIEW OF THE RESULTS OF 300 ASPIRATIONS. *R. E. Meatteringham and L. F. Ackerman*. From the Department of Pathology, The Ellis Fischel State Cancer Hospital, Columbia, Missouri. *Surg. Gynec. & Obst.* 84: 1071-1076, 1947.

Details of the technic of aspiration biopsy are given and the simplicity of the procedure is emphasized.

In no instance in the 300 aspirations did serious complications result and there were no cases in which fungation from the needle puncture occurred. One hundred and ninety-seven of the 300 aspirations were successful in that either tumor or lymphoid tissue was secured. Of these, 160 showed the presence of metastatic cancer. One hundred and three cases represented technical failure to obtain sufficient tissue but subsequent clinical course proved only 34 of these to be in error in that the patients subsequently developed cancer.

The greatest value of this technic is in the diagnosis of metastatic cancer. It is of much less value in the diagnosis of malignant lymphomatous disease since it usually is necessary to have an entire lymph node for examination in order adequately to establish this diagnosis.

I F R

ROENTGEN THERAPY IN HODGKIN'S DISEASE *T. B. Merner and K. W. Stenstrom* From the University of Minnesota Medical School, Minneapolis. *Radiology* 48: 355-368, 1947.

The authors of this article review in some detail the entire subject of Hodgkin's disease from the point of view of history, etiology, clinical diagnosis and differential diagnosis, and pathological distribution, and then summarize the modes of x-ray therapy with regard to technic and results. Their own experiences have led them to formulate a procedure of irradiation which is somewhat different from that of others.

There are 3 principles in this technic. Recurrences of Hodgkin's tissue are more radioresistant than the original areas, hence it is considered advisable to give a relatively heavier dose at the start of therapy. By the same token, the total amount of irradiation is given in as short a time as possible, not exceeding 2 weeks. Furthermore, since the site of recurrence is unpredictable, prophylactic irradiation is not utilized. The authors' technic, correspondingly, consists of intensive irradiation as soon as the diagnosis is made, a full course of treatment being given to each area involved, starting with the adenopathy which is giving the worst symptoms. Each course consists of between 1000 and 2000 tissue roentgens given in not over 14 days. By this method, the authors have, in a series of 185 cases, a 5-year survival rate of 21 per cent, and a 10-year survival of 8 per cent.

This report discusses, in passing, local resection of Hodgkin's tissue with subsequent irradiation, and discards it in favor of heavy irradiation. It also mentions ordinary spray therapy, as well as prolonged spray therapy in small doses, only to prefer heavier intensive irradiation. There is no discussion of therapy with the nitrogen mustards.

BLOOD COAGULATION, ANTICOAGULANTS AND HEMORRHAGIC DISEASES

A PHOTOMETRIC ANALYSIS OF THE REACTIONS OF BLOOD COAGULATION *J. Lem* Department of Zoology, Syracuse University, Syracuse, N. Y. *J. Cell & Comp. Physiol.* 30: 43-77, 1947.

When fibrin is formed during coagulation there is a progressive increase in turbidity. Photometric methods were devised to measure the light scatter and optical density during this process. Nonclottable proteins influenced the optical properties of this system and were believed to enter into the fibrin structure by being trapped in the process of fibrin formation. Evidence was presented to indicate that the clotting of fibrinogen by thrombin occurs in two stages. First the thrombin activates some of the fibrinogen, then these activated molecules react with nonactivated fibrinogen in a progressive polymerization reaction.

O P J

THE USE OF DICUMAROL AS AN ANTICOAGULANT: EXPERIENCE IN 2,307 CASES *E. V. Allen, E. A. Hines, Jr., W. F. Kvale and N. W. Barker* From the Division of Medicine, Mayo Clinic, Rochester, Minnesota. *Ann. Int. Med.* 27: 371-381, 1947.

Experience over a six year period with dicumarol is reported. Complications due to the use of the drug were limited to a 3.4 per cent incidence of hemorrhage which was considered serious in 1.8 per cent and included 2 cases of fatal bleeding. In a group of 819 patients with either pulmonary emboli or peripheral venous thrombosis there was a 2 per cent incidence of a further vascular complication while under

therapy The one fatal pulmonary embolus occurred after the patient's prothrombin had returned to normal These data show a marked reduction in expected mortality when compared with its incidence without anticoagulant therapy This report further justifies the spirit of general enthusiasm over the use of anticoagulants in thrombo-embolic disease

C A F

THE ORIGIN AND THE PHYSIOLOGY OF HEPARIN THE SPECIFIC THERAPY IN THROMBOSIS *J E Jorpes* The Caroline Institute, Stockholm, Sweden *Ann Int Med* 27 361-370, 1947

This article comprises a concise authoritative review of the origin, chemistry, action and therapeutic applications of heparin The material is dealt with more fully in the author's monograph on Heparin in Thrombosis, 1946 edition

C A F

CONCENTRATED AQUEOUS HEPARIN A NEW FORM OF INTRAMUSCULAR ADMINISTRATION *D Stats and H Neubof* Mt Sinai Hospital, New York *Am J M Sc* 214 159-162, 1947

Concentrated aqueous heparin was used containing 100 mg/cc and injected intramuscularly at 8 to 12 hour intervals in doses of 50 to 180 mg Maximum effect was attained 4 to 6 hours after injection In 2 per cent of injections local reactions were observed consisting of a small nodule or local discomfort This was felt by the authors to be a simple, safe and therapeutically satisfactory method of administration of heparin

Single injections, however, showed considerable variation in duration of action and insufficient data is reported for the reader to judge the predictability of anticoagulant effect on repeated injections

C A F

SOME OBSERVATIONS ON BLEEDING TENDENCY IN THROMBOCYTOPENIC PURPURA *J G Allen, G Bogardus, L O Jacobson, and C L Spurr* University of Chicago Medical School, Chicago, Illinois *Ann Int Med* 27 382-395, 1947

In this very interesting preliminary report the authors question whether the amount of circulating heparin may be increased in thrombocytopenic purpura By titration of heparinized blood against varying concentrations of protamine sulfate, they find that a greater amount of protamine is required to return the clotting time to normal in thrombocytopenic patients than in controls

Toluidine blue (2.5 mg/kilo body weight) was injected intravenously into 6 patients with thrombocytopenia in view of its known antagonism to heparin Four of these patients had leukemia and 2 had idiopathic thrombocytopenic purpura To judge from the illustration presented, the patients experienced dramatic remission in spontaneous purpura Platelet counts and bleeding times did not appear to be affected, and the authors emphasize that bleeding from ulcerated areas may be little improved Certain inconsistencies in the behavior of the patients to treatment along with the as yet limited data make it necessary to withhold any definite opinion as to the therapeutic value of antiheparin drugs in thrombocytopenic purpura

RADIOACTIVITY AND RADIOACTIVE ISOTOPES

EFFECTOS DE LA ENERGÍA ATÓMICA EN LA SANGRE (THE EFFECTS OF ATOMIC ENERGY ON THE BLOOD) *Sir Lionel Whitby* *La Prensa Médica Argentina* 34 14, 648, 1947

The deleterious effects upon the blood of atomic energy and high voltage x-ray brings up the necessity for a thorough study of the problem, and of the more practical methods of immunization

The penetrating and pernicious effects of the radiations are similar to those produced by the gamma rays of radium. There are three such effects (1) those produced by a sudden and intense irradiation, as observed among the victims of atomic bomb explosion, (2) those produced by repeated small, well tolerated doses, as observed in workers with radioactive substances and in investigators of nuclear physics, and (3) the effects secondary to continuous internal irradiation given off by radioactive substances accumulated in the marrow

The inhabitants of Hiroshima and Nagasaki subjected to intense and penetrating acute irradiation, showed, first, a latent period, then granulocytopenia, which occurred during the first three weeks, three to five weeks later, thrombocytopenia, with hemorrhagic diathesis, made its appearance, and from five to seven weeks after the explosion, cases of aplastic anemia developed. The sternal marrow in these cases, was found aplastic, physiologically if not always anatomically

Bones absorb radium, thorium, and radioactive calcium and strontium. The bone marrow is subjected to a continuous bombardment of destructive alpha rays, as observed in workers in the manufacture of luminous watches. Aplastic anemia with an aplastic marrow, or with a hyperplastic impotent marrow, develops as a result of this internal irradiation, and the hematologic picture is similar to that observed in the victims of atomic bomb explosion

R M S

THE MEDICAL USE OF RADIOACTIVE ISOTOPES I RADIOACTIVE ISOTOPES IN HEMATOLOGIC DISTURBANCES AND NEOPLASMS *B E Hall and C H Watkins*, From Division of Medicine, Mayo Clinic, Rochester, Minn *Am J M Sc* 213 621-628, 1947

Since radiophosphorus is chiefly deposited in the bone and bone marrow, it is understandable why its therapeutic value should be tested for modifying disturbances in the hematopoietic organs. Hall and Watkins review the cases reported in the literature and add some of their own. Radiophosphorus therapy is an effective method of controlling polycythemia vera. Besides the high cost of material another disadvantage is that the occurrence of leukemia may be accelerated

O P J

NEWS AND VIEWS

The Metropolitan Life Insurance Company, New York, reports that leukemia takes more than 6,000 lives annually in the United States, many of them among children. The death rate reported from leukemia is said to have more than doubled in twenty-five years and is more than five times that of infantile paralysis, about one and one-half times that of measles, scarlet fever, whooping cough and diabetes combined, and almost equal to that of appendicitis.

The Surgeon General, U. S. Public Health Service, has appointed an Advisory Board whose function is to designate the proper names for the several anti-Rh blood typing serums licensed under the Biologic Law. The desire is to have recommended a system of nomenclature which will be adequate to cover this phase of human genetics and which can be readily adapted to clinical use, medical teaching, and laboratory diagnosis. Members of the Board are William B. Castle, Jr., Professor of Medicine, Harvard Medical School, Maxwell M. Wintrobe, Professor of Medicine and Department Head, School of Medicine, University of Utah, and Laurence H. Snyder, Professor of Medical Genetics and Dean of the Graduate School, University of Oklahoma.

At a Conference on Nomenclature of the Rh factors which was held at Washington, D. C., on October 20, 1947, and continued through the 21st, the Board heard evidence from various persons qualified in this field. It is expected that an official report of the proceedings will shortly be available.

A letter regarding the above conference has been received from Dr. Alexander S. Wiener.

To the Editor

The National Institute of Health recently held a conference on nomenclature of the Rh factors, in order to settle the problem of labeling Rh antisera. The purpose of this letter is to present my own reaction to this meeting.

As far as I could determine, the consensus of those present was that the original designations of the Rh types as rh , rh' , rh'' , $rh'rh''$, rh_0Rh_1 (or Rh_0'), Rh_2 (or Rh_0'') and Rh_1Rh_2 , based on the designation of the three common Rh antisera as anti- Rh_0 , anti- rh' , and anti- rh'' , be retained as the standard nomenclature. A number of those present suggested that in addition certain alternative designations, using the letters C-D-E, should be added in parentheses when labeling antisera. The present writer maintains that such a duplicate method of designation is entirely unnecessary and will only cause confusion. Experience with the four Landsteiner blood groups has already proved that confusion is avoided only by the use of a single rational and descriptive nomenclature.

At the meeting the present writer had the opportunity to present his original findings on which the standard nomenclature is based, and also to hear the views of other workers in the field. This has finally made clear the mysterious attraction of notations using symbols like XYZ_{xyz} , or Rh_{12345} , instead of the symbols Rh_0 , rh' , rh'' , Hr' and Hr'' (evidence for Hr_0 has still not been published). Obviously, to many people notations like I, II, III, IV, are much easier to remember than O, A, B, and AB. In the former case one has but to learn that there are four blood groups. To remember O, A, B, and AB on the other

hand one is compelled to learn that there are two substances A and B, in the blood which form four combinations. This additional effort is quickly repaid, however, in the case of laboratory workers who must be familiar with Landsteiner's rule concerning the reciprocal relationship of agglutinogens and agglutinins, and also for medicolegal experts, to whom, for example, the statement that parents of groups O and AB can only have children of groups A and B is much more intelligible than $I \times IV$ can only yield II and III. Similarly, it seems easier to learn that there are three factors Rh_1 , Rh_2 , Rh_3 , or XYZ than that there are three factors, Rh_0 , Rh' and Rh'' . Actually, by taking a little extra effort to understand the original nomenclature, one learns at the same time of the special serologic, genetic and clinical position of factor Rh_0 and that rh' and rh'' are related very much as A and B are to each other. Thus, by applying what one already knows of the four blood groups, one *immediately* knows the eight Rh types, while those using designations like XYZ must start from the beginning and perhaps never really grasp the subject. It is easy to see, for example, why the mating $rh \times Rh_1 Rh_2$ yields almost 50 per cent type Rh_1 and 50 per cent type Rh_2 children with only rare children of types rh' and rh'' while this is completely unintelligible when written as $Neg \times Rh_{123}$ or xyz or XYZ .

In addition, the symbol Rh has an important descriptive significance, indicating the origin of our knowledge of this antigen through the study by Landsteiner and Wiener of immune serum prepared by immunizing experimental animals with the blood of rhesus monkeys, which antisera, these workers found, also agglutinate the bloods of about 85 per cent of Caucasian individuals. It was because the first antisera were prepared with the blood of rhesus monkeys that the symbol Rh (the first two letters of the name Rhesus) was chosen to designate the antigen, while anti- Rh was the natural name for the corresponding antiserum. When, with the aid of antisera of human origin, it was later discovered that there are other related antigens in human blood, it was only natural that names be selected for these antigens which showed their relationship to the Rh_0 antigen originally discovered by Landsteiner and Wiener, but at the same time indicated their characteristic differences.

One final point which everyone seems to have overlooked is that as early as 1942 when only Rh_0 and rh' had been found by me, I considered the possibility that these factors might be transmitted by genes that were linked, independent or allelic (WIENER, A. S. Blood Groups and Transfusion, ed. 3, 1943, p. 254). When statistical analysis of the available data proved that the hypotheses of linked and independent genes were incorrect, we explained the hereditary transmission of the four Rh types known at that time by postulating the existence of four allelic genes. When later rh'' was found, it hardly seemed necessary to repeat the evidence against linkage and independent assortment, and so the theory was merely extended to include six standard allelic genes, to which British workers added the seventh and rarest gene R^{*5} . Thus, Fisher's theory besides being wrong, is not original since it had been considered and discarded by me more than two years before he proposed it. Incidentally, based on the theory of multiple allelic genes, the existence of type $rh'rh''$ and its frequency of only about 1 in 10,000 was predicted by me and later confirmed. Also the existence of factor rh''' was predicted by me, only to be confirmed by workers in England.

In conclusion, it should be apparent from the foregoing that a recent report published in this journal (Blood 2: 204-27, March, 1947), advocating the adoption of Fisher's notations in order to "clarify the nomenclature problem" is based on incorrect and incomplete information. Actually there is no nomenclature problem except the one that would be created by the unnecessary introduction of duplicate or triplicate systems of notations. Therefore, it is hoped that the publication of this letter will serve to correct any damage caused by the misleading report referred to above.

Alexander S. Wiener

Office of the Chief Medical Examiner, New York, New York.

The report, referred to above, published in this journal was entirely reportorial and represented the consensus of the workers who met at Dallas and Mexico City in November 1946 to discuss problems relating to the Rh factor. The report itself was, we believe, clearly written and therefore not 'misleading'. Dr. Wiener probably objects to the conclusions of the group which met, discussed and arrived at a decision on a question of nomenclature. This decision happens to be at variance

with Dr Wiener's concepts. It will be of interest to obtain the reaction of other readers to Dr Wiener's comments.

Editor

The following items have been received from Dr José Oria, São Paulo, Brazil.

The Department of Histology and Embryology of the Medical School of the University of São Paulo, Brazil has been doing histologic research, both human and comparative, of blood and hemopoietic organs for about twenty years. In charge of this work is Assistant Professor Dr José Oria.

Several general and individual contributions to Hematology have had their origin from this department. Thus, the clinical hematologic service of the University is now being carried on in the Central Laboratory of the Clinical Hospital (of the University), under the direction of Assistant Professor of Internal Medicine, Dr Michael Jamra. This service conducts the hematologic examinations of the entire hospital.

Clinical and cytohematologic studies have been published from or are being carried on in both departments. Among others should be mentioned the most recent on megakaryocytes, mast-cells, plasmacytes, artificial segmentation of the blood elements in oxalated milieu (Dr José Oria), on hypersegmented neutrophils (Dr Oria and Dr S. Yoneda), multipolar mitoses in megakaryocytes, drepanocytic anemia, hemophilia, metabolism in pernicious anemia. The karyologic curve of bone marrow in vivo under certain conditions is being studied by Dr Fernando T. Mendes. Dr Jamra and Dr Mendes (of the Clinical Hospital of São Paulo) are in constant contact with the Department of Histology and Embryology of São Paulo, in order to coordinate these services.

The Section of Cellular Physiology of the Department of Histology and Embryology (Dr Piero Manginelli, former Research Associate with Dr R. Chambers) is initiating cytologic investigations in blood.

Dr Lucio Carvalho Lima, voluntary assistant in this Department, is now at work in Dr M. M. Wintrobe's laboratory at the University of Utah.

Dr Carlos A. Lacaz and co-workers have written on the Rh factor in São Paulo. Their work is being performed in the Department of Microbiology and in the Clinical Hospital of the same University. One of Dr Lacaz's co-workers is Dr Humberto Costa Ferreira, who worked recently with Dr Nathan Rosenthal in New York.

The eighth annual meeting of the Italian Society of Hematology was held in Pavia, June 29 - 30, 1947. The French and Swiss Society of Hematology were represented.

The presidential address was given by Prof. Di Guglielmo of Naples. Drs. Conte-Marotta and Di Guglielmo Jr. spoke on 'Urinary Factors in Leukemia,' Dr Fieschi spoke on 'Marrow Cultures in Leukemia,' Dr Storti on 'Leukemia as Neoplasm,' Dr Baserga on 'Recent Advances in Pathogenesis and Therapy of Leukemia,' and Dr Morganti on 'The Rh Factor.'

The following letter, dated July 20, 1947, from Dr Paul Chevallier of Paris, addressed to "Mr President of the American Society of Hematology" has been received at the editorial office. It was translated by Dr H Tagnon. At present, no American Society of Hematology has been constituted.

Mr President

I have the honor of informing you that at the Italian Hematologic Congress June 29-30, 1947 it was decided to create an Academy of Hematology. The word Academy was chosen for the time being rather than Society or Association, to indicate that the number of members is limited and that, in agreement with the meaning of the French word *academique* no other condition should be considered except that of hematologic science.

For the time being, the Academy has been qualified as European, this because no representative from another continent was present. The founders have the strongest desire that it be International.

It was also decided that in the present world contingency, the general secretary (permanent) could not be otherwise than a Swiss citizen with perfect neutrality. Sr Undritz was elected but his definite acceptance is conditioned on the decision of his superiors.

I was elected President and this is why I am writing you for this embryo of an Academy.

In order to keep the Academy young, the active members, with the same privileges, have been divided into *seniors* (above 65 or 70 years, or elected for more than the last 10 years), without limitation in number, and *juniors*, whose number has been provisionally limited to 100 (for Europe alone).

In addition there will be members who will participate in the scientific proceedings but not in the administration. These are corresponding members and *Membres agrees*, appointed for 5 years and chosen among those of the young who show definite promise but as yet have not attained a definitive status as hematologists.

In those countries having a National Hematologic Society, membership will depend on nomination by the National Society.

The Academy will hold annual meetings, in a different country, lasting two days, and will study various problems submitted. One meeting will be devoted to presentation of scientific and clinical material by the hematologists of the region where the meeting is held.

It is projected to have the first meeting (study of constitution, by-laws, etc.) in Paris, in May 1948.

In the meantime, the provisional Bureau (Paul Chevallier, di Guglielmo, Lambin, Undritz) is commissioned to choose a certain number of known hematologists to form the nucleus of the Academy.

We have the great hope that you will join us and bring us your admirable vitality. On you depends the International rather than European character of the Academy.

If, as we hope, you agree, you will kindly send us the names of people whom your Society thinks should be Founder members, and a list of the candidates for election to vacant seats.

We will also have to discuss with your representative the problem of the total number of junior members of the *International Academy*, the junior members from Europe being limited to one hundred.

I beg you to receive, Mr President, the expression of my very high consideration.

Paul Chevallier

International Society of Hematology

Much progress is being made in the development of this Society, which evolved from the highly successful Rh and Hematology Congress held in Dallas and Mexico City in November, 1946. The officers are: President, Dr Joseph M Hill, Dallas, Vice-President, Dr Eduardo Uribe Guerola, Mexico City, Secretary, Dr Sol Haberman, Dallas, Treasurer, Dr Stanbury, Toronto.

Meetings are to be held bi-annually, probably during one of the summer months, so as to coincide with vacation plans and travel. The first of these meetings will

be held at the Hotel Statler, Buffalo, during August 24-27 inclusive. Tentative plans indicate that these four days will be divided as follows: one day, red cell problems, one day, immuno-hematology, one-half day, white cell problems, one-half day, coagulation problems, one-half day business, one-half day entertainment.

The following Committees have been appointed:

Program Committee

Witebsky, Ernest, Chairman	Buffalo General Hospital, Buffalo, New York
Diamond, Louis K	The Blood Grouping Laboratory, 300 Longwood Ave., Boston, Mass
Whitby, Sir Lionel	Regius Prof. of Physics, Department of Medicine, University of Cambridge, London, England
Moore, Carl	600 S. Kings Highway, Washington University School of Medicine, St. Louis, Missouri
Guerola, Uribe Eduardo	Ponciano Arriaga 26, Mexico, D. F.
Seegers, Walter	Wayne University, Detroit, Michigan
Snyder, L. H.	Oklahoma University, Dean of Graduate School, Norman, Oklahoma

Constitutional Committee

Davidsohn, Israel, Chairman	Mt. Sinai Hospital, Department of Pathology, California Ave. and 15th Place, Chicago 8, Illinois
Gutierrez Villegas, Luis	Plaza de la Republica 52, Mexico, D. F.
Robb Smith, A. H. T.	University of Oxford, Director of Pathology, Radcliffe Infirmary, Oxford, England
Tocantins, L. M.	Jefferson Medical College and Hospital, Philadelphia, Pennsylvania

Blood Bank Institute

A Blood Bank Institute was held in November 1947 at Dallas, Texas in conjunction with the William Buchanan Blood Center. Eighty-three representatives of blood banks from various parts of the country attended and participated in the program. At the conclusion of the program an American Association of Blood Banks was formed. Details regarding both the institute and the new Association will be published in a forthcoming issue of this Journal.

To the Editor

In two papers^{1, 2} appearing in recent issues of *Blood*, reference has been made to lysolecithinase as the enzyme which converts lecithin to lysolecithin.

This terminology is, of course, incorrect: an enzyme is not named from the product it forms. Following the usage of Belfanti³ the enzyme in question is commonly referred to as lecithinase A. It would be unfortunate if the incorrect term were generally adopted by hematologists.

BOOK REVIEW

The Coagulation of the Blood Investigations on a New Clotting Factor BY PAUL A. OWREN Oslo, J. Christian Gundersen, 1947

In this book, which was also published as a supplement to *Acta Medica Scandinavica* in 1947, Owren describes an unusual case of a hemorrhagic diathesis in a woman with increased coagulation time in which, at first sight, prothrombin appeared to be at fault. All the other elements of the blood coagulation reaction were apparently normal, quantitatively and qualitatively. Furthermore, laboratory findings revealed no apparent cause for the hemorrhagic tendency in this patient other than a severe hypoprothrombinemia as determined by the Quick method. Subsequent investigations by the author demonstrated that addition of small amounts of prothrombin free plasma produced a great decrease in the prothrombin time of the patient and consequently an apparent increase in the prothrombin concentration as determined by Quick's method. Since Owren found that fibrinogen, prothrombin, thrombokinase, and calcium were all present in normal amounts he concluded that some factor other than those usually associated with coagulation was at fault. By precipitation with weak acids, dialysis, and salting out methods, Owren was able to prepare a material which apparently was lacking in his patient and which he terms Fraction 5. This factor he claims is necessary for normal coagulation of plasma and is found in normal plasma after the removal of calcium, prothrombin, fibrinogen and by means of Chamberland filtration, thrombokinase. The addition of Fraction 5 to the customary Quick setup results, according to Owren's data, in a markedly decreased prothrombin time. Owren assumes that Fraction 5 requires either prothrombin or a portion of the prothrombin complex to form a second new substance, Fraction 6, in the presence of calcium or thrombokinase. Fraction 6 which has as yet not been isolated, reacts with prothrombin in the presence of calcium to form thrombin which in turn produces the fibrin clot from fibrinogen. Owren has suggested the term proprothrombinase for Fraction 5 and prothrombinase for Fraction 6. He advances the view that Fraction 6 is a proteolytic enzyme capable of converting prothrombin to thrombin. He replaces the older terminology of Bordet and Nolf by a new term, cytokinase, which replaces the old term cytozyme and thrombozyme. Owren's theory of blood coagulation, then, may be schematically described as follows:

1. Factor V Prothrombin (?) Cytokinase Ca Prothrombinase
2. Prothrombin Prothrombinase Ca Thrombin
3. Fibrinogen Thrombin Fibrin

Owren's theory has been republished in part in *Lancet* and has been editorialized by that journal.

The acceptance of two new members of the coagulation family is a serious development requiring careful consideration on the part of all investigators in the field and undoubtedly much investigation will be stimulated as a result of Owren's work. There is, however, a considerable danger involved in accepting this new concept at the present time. The methods of preparation of Fraction 5 are, in a great many ways, similar to those used by Taylor and associates for the preparation of globulin substance or antihemophilic globulin. Plasmas may be prepared free from formed elements and from prothrombin and fibrinogen, but which still contain significant amounts of globulin substance by precipitation with weak acids or on dialysis. There is also a similarity between Fraction 5 and the so-called activating globulin of Seegers. Since the greatest difficulty of the study of blood has been the failure of investigators to relate the various preparations they have made with preparations of others having similar chemical properties and physiologic functions, it would seem highly important that Owren's Fraction 5 be fully investigated definitively before it can be accepted as a new factor. Fraction 6 which has not yet been isolated in many of its properties, resembles the proteolytic enzyme described by Tagnon and his associates and which we now know can be prepared in free form by the fractionation procedures of Cohn. Such proteolytic enzymes are an important consideration in the theory of Ferguson. Furthermore, there is some evidence that the postulation of a substance such as Fraction 6 is unnecessary when one considers the coagulation

properties of freshly prepared and old serum. Owren's work is a challenge for further investigation in an attempt to clarify the coagulation situation. No theory at present competently explains all the facts.

In addition to the presentation of his new hypothesis, Owren has reinvestigated the kinetics of the coagulation reaction from many angles and has re-examined the physico-chemical properties of the classic components of the coagulation reaction. In chapter 8, he attempts to bring his present investigation into relation with the older theory of blood coagulation.

Unfortunately, a great deal of work in the United States since 1941 was not available to the author, and as expressed by Owren, only Danish and scattered British and American articles have been available for reference. No student of the blood coagulation problem should fail to review Owren's work in an attempt to relate the new components to the classic theory.

F. H. L. Taylor, Boston

CONGENITAL HEMOLYTIC JAUNDICE THE PATHOGENESIS OF THE "HEMOLYTIC CRISIS"

By PAUL A OWREN, M D

THE MOST serious and dramatic complication in congenital hemolytic jaundice is the occurrence of a hemolytic crisis. This manifests itself by a sudden catastrophic fall in the hemoglobin and red cell count which in the course of a few days can produce a critical, sometimes fatal condition in the patient.

The immediate cause of these acute crises is unknown, but most hematologists seem to be agreed, as far as the pathogenesis is concerned, that the acute anemia arises because of a sudden greatly increased destruction of the red cells, a view which is expressed in most of the standard text books and papers on this subject (Meulengracht 1918, Lord Dawson of Penn 1931, Heilmeyer 1935, Schulten 1939, Vaughan 1936, Kracke 1941, Whitby and Britton 1946, Wintrobe 1946, and others). The terms 'hemolytic crisis,' 'hemoclastic crisis' and 'crise de deglobulisation' express this view.

I shall refer later to investigations which show that this generally accepted view may be erroneous. It will be shown that the anemic crises are not due to increased hemolysis, but to a sudden cessation in formation of the new red cells because of an acute aplastic crisis in the blood forming tissue of the bone marrow.

MATERIAL

The investigation covers crises in 6 cases of congenital hemolytic jaundice. The first 4 cases, which occurred in the members of the same family, were observed in 1942. The following members of this family became ill within a few days of each other: (1) An 8 year old girl, (2) her grandfather of 59, (3) her father aged 40, (4) her father's brother aged 38. The fifth case was a man of 22 whose family connections are shown in figure 1. This family tree is of special historical and clinical interest for the following reasons: 3 members of the second generation had anemic crises in 1890, 10 years before Minkowski's description of congenital hemolytic jaundice. This incident was described by Koren in 1891 as '3 cases of acute pernicious anaemia in the same family,' and Torup (1891) suggested that the anemia was produced by an acute carbon monoxide poisoning. This erroneous explanation resulted in the subsequent view that carbon monoxide poisoning can produce marked anemia. The true reason for the incident was given by Holst in 1917. The sixth case in a woman of 20, belonged to a third family.

In all 6 cases the disease showed complete accordance with the criteria for hemolytic jaundice, which was first described by Minkowski in 1900 and Chauffard in 1907. The patients presented the following characteristics: jaundice without bilirubin in the urine, anemia, splenomegaly, increased fragility of the red cells.

to hypotonic saline, increased number of reticulocytes in the blood, spherocytosis and familial incidence of the disease

All patients were examined several times after complete recovery from the crisis, two of them also before onset of the crisis. Representative findings in the peripheral blood are given in table 1

CLINICAL AND HEMATOLOGIC FINDINGS DURING THE COURSE OF THE CRISES

In all 6 cases the crises began quite suddenly with a rise in temperature, cases 2 and 4 having rigors, and case 1 abdominal pain and vomiting. The temperature swung irregularly between 38° C and 39.5° C, lasted about ten days and returned to normal at the same time as the recovery of the blood picture began. Jaundice

decreased in all cases with the development of the anemia (cf figs 2, 10, 12), and the size of the spleen remained unchanged during the course of the crisis, as far as its size can be determined clinically. These points are emphasized, as the literature states that the jaundice as well as the size of the spleen increase during the crisis.

FIG. 2. CASE 4. MALE 38 YEARS. BLOOD AND MARROW FINDINGS

THE ERYTHROPOIETIC FUNCTION

The typical hematologic findings during the course of a crisis are given in figure 2 which gives the blood and marrow findings in case 4, a man aged 38.

Eight days before he became ill, this patient went to the hospital with his father, case 2, and a full clinical and hematologic examination was made at that time. He presented all the characteristic signs and symptoms of hemolytic jaundice (cf table 1), and was told to report for admission to the hospital immediately if he felt ill. Eight days later he felt cold and chilly, and his temperature started to rise,

the following day he reported to the medical ward. In this way we had a unique chance to collect observations just before the crisis as well as during its development. As a rule patients with "hemolytic" crises do not come under observation before the anemia is fully developed, as it is the anemic symptoms which bring the patient to the doctor. This fact seems to be the reason that the first phase of the crisis, the onset of anemia, has not been fully reported until now.

It is evident from figure 2 that the anemic phase is characterized by the following findings: the hemoglobin and red cell count fall rapidly, and in the course of about six days are reduced to about half of the original value. The color of the serum

TABLE 2—Case 4 Number of nucleated cells in bone marrow during crisis

	Eight days before crisis	Days after onset of crisis

Mitotic normoblasts	1.1	—	—	0.9	1.0	1.2

becomes normal again, and the reticulocytes disappear completely from the peripheral blood.

The reticulocyte disappearance points to the fact that the anemic phase is accompanied by a complete cessation of the erythropoietic function. This is fully confirmed by examination of the bone marrow. The upper part of figure 2 illustrates the number of erythroblasts per cu mm bone marrow. In the anemic phase there is almost complete aplasia of the erythropoietic tissue as is otherwise seen only occasionally in aplastic anemia. Remnants only of erythropoietic tissue are found in this period in the form of a very few stunted normoblasts, and scattered large characteristic immature cells. At the first sign of recovery we see active formation from these large cells of proerythroblasts (pronormoblasts) with subsequent development to macroblasts (basophilic normoblasts) and later polychromatic and orthochromatic normoblasts which in the course of a few days increase so that

they completely dominate the bone marrow picture in an excessively active proliferation (cf fig 2) This regeneration is immediately followed by a reticulocyte crisis in the peripheral blood, up to 30 per cent, with a subsequent quick recovery of the blood picture

Table 2 illustrates the relative rates of this regeneration The number of erythroblasts which, during the initial phase of the crisis, are reduced to about 3000 per cu mm bone marrow or 4-5 per cent of the total amount of nucleated cells, increase rapidly to about 300,000 per cu mm or to 80 per cent of the nucleated cells

FIG 3 CASE 4 BONE MARROW 8 DAYS BEFORE CRISIS THE ERYTHROPOIESIS DOMINATES THE PICTURE $\times 600$

The qualitative changes during this regeneration as they appear in the differential count are given in table 3 From this it is clear that the course of regeneration goes through the normal stages of proerythroblasts and macroblasts to the hemoglobin containing polychromatic and orthochromatic normoblasts

The photomicrographs verify this development Figure 3, which shows the bone marrow in this patient eight days before crisis, shows a typical and uncomplicated picture of hemolytic jaundice, the erythropoiesis dominating the picture and the more mature normoblast stages forming the most striking component On the fourth day of the crisis (fig 4) the picture is completely changed the erythroblasts have disappeared and the marrow consists almost exclusively of leukopoietic tissue, with myelocytes and promyelocytes predominating On the sixth day the picture is similar (fig 5)

FIG 4 CASE 4 BONE MARROW PICTURE ON THE FOURTH DAY AFTER ONSET OF CRISIS

The erythroblasts have almost completely disappeared and the marrow consists almost exclusively of leukopoietic tissue $\times 600$

FIG 5 CASE 4 SIXTH DAY OF CRISIS

The picture is similar to fig 4 $\times 600$

FIG 6 CASE 4 NINTH DAY OF CRISIS
The regeneration of proerythroblasts has started $\times 1000$

FIG 7. CASE 4 TENTH DAY OF CRISIS
Further maturation with increasing macroblasts $\times 1000$

Which cell in this marrow is the origin of regeneration of the red cells? As mentioned, preparations from this period show single large cells, 35 to 40 μ in diameter and with a basophilic protoplasm and leptochromatic nuclei. From these cells one can follow a uniform development to proerythroblasts (fig 6) from the ninth day of the crisis, and (fig 7) from the 10th day. At this time we find a regeneration of proerythroblasts in great quantities, together with a number of macroblasts (basophilic normoblasts), but not more mature forms. There are still no reticulocytes in the peripheral blood. Figure 8, taken two days later, shows an enormous increase in normoblasts and a great diminution in the proerythroblasts. On the

FIG 8 CASE 4 TWELFTH DAY OF CRISIS

Large increase of normoblasts and decreasing number of proerythroblasts $\times 1000$

fourteenth day (fig 9), we find large nests of polychromatic normoblasts. At this time the reticulocytes in the peripheral blood were increased to 30 per cent.

It is apparent from these findings that during the development of anemia the erythropoietic tissue of the bone marrow is in a temporary state of aplasia. The spontaneous recovery shows that the erythron has a quite fantastic ability to regenerate.

Figure 10 shows the course of the crisis in patient number 6, a woman aged 20. The color of the serum diminished and the jaundice disappeared. Reticulocytes disappeared from both peripheral and sternal blood, and recovery was heralded by a reticulocyte crisis. The sternal marrow was examined daily in this case, and showed similar changes as in the previous patient. The differential counts of

FIG 9 CASE 4 FOURTEENTH DAY OF CRISIS

Enormous increase of normoblasts Reticulocytes in peripheral blood 30 per cent

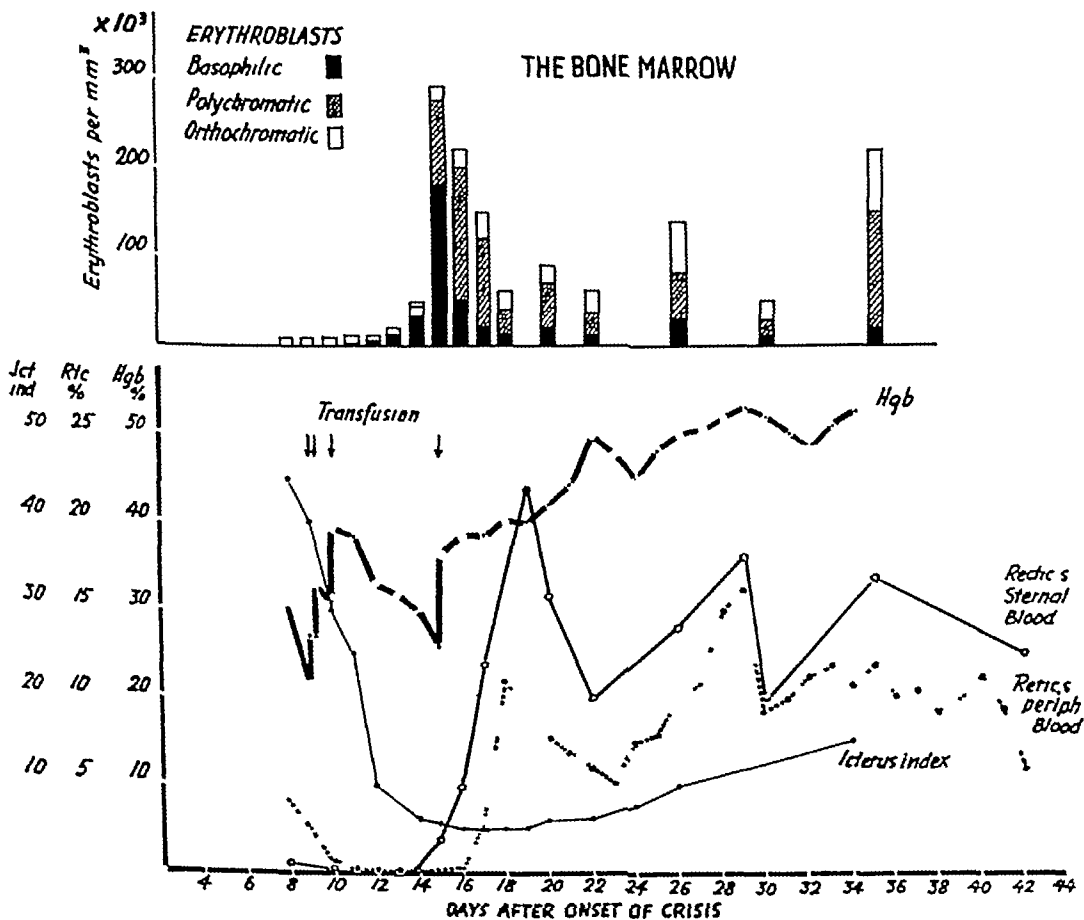

FIG 10 CASE 6 FEMALE 20 YEARS BLOOD AND MARROW FINDINGS

nucleated red cells is given in table 4, and the total number of nucleated red cells per cu mm of bone marrow is illustrated by the columns in figure 10. It follows that the crisis is accompanied by transient aplasia in the erythropoietic tissue as was demonstrated in the previous patient.

All 6 patients showed corresponding pictures. In table 5 are given the lowest blood values observed in the 6 patients during crisis. The reticulocytes disappear, severe anemia develops, granulocytopenia, and thrombocytopenia and the serum color is lowered to normal.

* Patients treated with transfusions

Figure 11 shows the reticulocyte counts in the 6 patients. On the whole the curves have the same form in that the reticulocytes disappear during the development of the anemia, and by recovery reticulocytosis appears in the peripheral blood ten to twelve days after the beginning of the crisis.

Another typical feature of the crisis is the diminution of the urobilin in the urine at the same time as the jaundice disappears, as seen in figure 12 from patient number 2.

Figure 13 from patient number 5, shows how the serum iron increases to pathologic value (in this case to 2007 per 100 ml) during the aplastic phase, subsequently to fall quickly. The concentration of uric acid in the blood also was in-

creased during the period of severe anemia up to 10 to 11 mg /100 ml (cf fig 13) and a fall to normal value with recovery

FIG 11 RETICULOCYTE COUNTS IN ALL 6 CASES

FIG 12 CASE 2 MALE 59 YEARS ILLUSTRATES THE DECREASING UROBILINURIA DURING THE CRISIS

If the patient is suffering from lack of iron during the period of rapid regeneration of hemoglobin, the iron deficiency may retard the regeneration. Figure 14 from patient number 6, shows a decrease of serum iron to 35 γ /100 ml. The rise of reticu-

The changes in the number of leucocytes and thrombocytes in the peripheral blood during the crisis are illustrated in figures 15a and b. In all cases the differential counts showed that the aplastic phase was accompanied by a granulocytopenia down to about 1000–2000 granulocytes per cu. mm (cf. table 5). The thrombocytopenia varied from 30 to 100,000 thrombocytes per cu. mm. In one of the patients (number 2) the thrombopenic phase was accompanied by a mild purpura. The granulocytopenic phase was not accompanied by any aplasia of the granulocytopoietic tissue. The number of leukoblasts and leukocytes per cu. mm of bone marrow was rather constant during the crisis as shown in table 2 and as may be calculated from table 4. The differential counts, however, showed a shift to the left during the granulocytopenic phase, with increasing number of promye-

lyocytes and myelocytes and decreasing number of mature forms. This event is illustrated in table 6 and points to the fact that the initial phase of the crisis apart from an erythropoietic aplasia is accompanied by an arrest of maturation of the leukopoietic tissue. The thrombocytopenia is likely to be explained in a similar way.

The number of lymphocytes and monocytes did not show any significant variation during the crises.

The recovery from crisis is heralded by leukocytosis as the first sign of improvement in the condition. The leukocytosis can attain a value up to 40,000 leukocytes per cu mm as in case 5 (cf. fig. 15a) and is accompanied by a shift to the left. A short time after the leukocytosis, an increase of thrombocytes appears, and finally the reticulocyte crisis occurs. This train of events was constant in all cases, and seems to bear a relation to the life cycle and rate of maturation of the respective elements of the blood.

A moderate azotemia was constantly found during the anemic phase. The concentration of blood urea increased to between 60 and 140 mg per 100 ml, and dropped to normal quite rapidly when the hemoglobin and red cell count began to increase.

DISCUSSION

The morphologic changes in the bone marrow which were demonstrated during crisis, together with the disappearance of the reticulocytes both from the peripheral and sternal blood, show that during the development of the anemia an acute aplastic condition is present in the erythropoietic tissue with complete cessation of the formation of red cells. The spontaneous recovery is characterized by a rapid regeneration accompanied by a reticulocyte crisis in the peripheral blood.

Can this transient aplasia in the erythropoietic tissue fully explain the development and symptoms of the crisis, or is there at the same time an increased hemolysis as it is usually assumed? As is stated before, there is no positive sign which points to increased hemolysis, on the contrary, the serum color and urobilinuria both decrease during the development of anemia. This was a constant finding in all cases, a condition which quite definitely contradicts the theory that an acute increase in the hemolytic processes is the reason for the crisis. The finding points to the fact that the total destruction has a tendency to decrease as the anemia increases. Thus, the formation of bilirubin is reduced, and the excretory capacity of the liver is sufficient to eliminate the coloring matter. The theory that jaundice increases during the crisis does not appear to be founded on objective investigations, and we believe it to be erroneous.

On the other hand, it is not a difficult matter to show that a sudden cessation in the formation of red cells in hemolytic jaundice will necessarily cause a rapid onset of anemia. When blood formation ceases, the rate at which anemia develops will be dependent on the lifetime of the red cells. Figure 16 shows that red cells from a patient with congenital hemolytic jaundice transfused to a normal individual, have a maximal lifetime of approximately fifteen days, while normal red cells transfused to a patient with hemolytic jaundice live about 110 - 120 days.

The test is carried out on another of our patients with compensated anemia, and the percentage of surviving red cells is determined with the help of Dacie and Mollison's (1943) modification of Ashby's (1919) differential agglutination technic. The result is in accordance with earlier investigations, among others, those carried out by Dacie and Mollison (1943). These transfusion experiments show that the fundamental pathologic disturbance in congenital hemolytic jaundice is associated with the actual red cells and not with any pathologically increased destructive function of the spleen or the remaining reticulo-endothelial system as maintained by Heilmeyer (1935), Bergenheim and Fåhræus (1936) and others. The determining feature of the short life span of the red cells is their spherocytic abnormality. There is reason to assume that this lifetime is the same in the patient as after transfusion to a normal individual.

FIG 16 THE SURVIVAL OF ERYTHROCYTES FROM A CASE OF CONGENITAL HEMOLYTIC JAUNDICE, MAN AGED 38, TRANSFUSED TO A NORMAL RECIPIENT, AND THE SURVIVAL OF NORMAL ERYTHROCYTES TRANSFUSED TO THE PATIENT (FROM OWN INVESTIGATIONS TO BE PUBLISHED)

If we reckon an average lifetime of fifteen days in hemolytic jaundice, a sudden cessation in the formation will result in reduction in the number of circulating red cells to half in approximately seven to eight days, and in their total destruction in about fifteen days. On inspecting the curve of increasing anemia in figure 2, we find a similar course, with a reduction of the red cell count to about half in approximately six days, and if the curve is continued, total destruction in approximately fifteen days. This curve is an expression of the lifetime of the red cells in the patient as the formation is at a standstill, and we find that this completely corresponds to the lifetime of red cells from cases of hemolytic jaundice transfused to a normal individual (cf fig 16).

The development of the anemia, therefore, can be satisfactorily explained by the deficient blood formation, and there is nothing that points to the fact that these relapses are accompanied by any increase of the hemolytic or destructive processes. The remaining symptoms of the crisis also have a natural explanation from this point of view.

The increase in serum iron during the aplastic phase is a consequence of deficient consumption during this period, and the subsequent fall at the same time as the excessive hemoglobin formation sets in needs no further explanation.

The changes which are demonstrated in the granulocytes explain former incongruities on this point. Most hematologists have found leukocytosis as a typical feature in the symptomatology of the crisis, while others have found leukopenia. The varying findings are due to the investigations being carried out at different times during the development of the crisis. It ought to be emphasized further that the neutrophilic leukocytosis is only an expression of rapid regeneration in a similar manner, which can be seen after hemorrhages, and in liver therapy in pernicious anemia. This leukocytosis can not be made to account for any infectious etiology of the crisis as has been suggested.

The increase in the blood urea which occurs seems to be the result of a failing kidney function owing to the severe anemia, and the increase in uric acid in the blood may probably be related to the same disturbance.

Some earlier investigations have shown a very low reticulocyte count during crisis (Barber 1934, Murray-Lyon 1935), but these findings have not been further investigated. Lyngar (1942) found in one case, however, signs of reduced erythropoietic tissue in the bone marrow, and indicated a possibility of reduction in formation of the red cells as a link in the pathogenesis of the crisis. Dameshek (1941) has reported cases with leukopenia, thrombocytopenia and reticulocytopenia during crisis, and discusses these findings in the view of Heilmeyer's theory of a sudden splenic hyperactivity as the cause of the hemolytic crisis.

In conclusion, we can say from the investigations reported, that they support the opinion that congenital hemolytic jaundice is due to an abnormality in the red cells which makes them less resistant to the destructive function of the normal reticulo-endothelial system. The lifetime is short and the compensatory new formation is therefore active.

The crises are due to a sudden cessation in the formation of red cells and a depression of the formation of granulocytes and thrombocytes because of a transitory acute aplasia in the erythropoietic tissue together with a maturation arrest in the granulocytopoietic and thrombocytopoietic tissue. The crises ought, therefore, to be called aplastic crises, and not hemolytic crises.

The releasing factor of this acute aplasia is unknown, but the appearance of several cases together suggests that they can be produced by some extraneous reason, possibly infective.

SUMMARY

Six cases of congenital hemolytic jaundice with "hemolytic" crises are reported. It is demonstrated that during the development of the anemia an acute aplastic condition is present in the erythropoietic tissue of the bone marrow with complete cessation of the formation of red cells. The reticulocytes disappear from the blood, jaundice, serum bilirubin and urobilinuria decrease to normal values, and the serum iron increases. This period is further characterized by leukopenia and thrombocytopenia.

The spontaneous recovery is caused by a rapid regeneration of the erythropoietic tissue resulting in a marked reticulocytosis in the peripheral blood, and there is also leukocytosis, an increase in thrombocytes and a rapid fall of serum iron

During the period of severe anemia an increase in the blood urea and uric acid occurs

Transfusion experiments revealed an average lifetime of approximately fifteen days for the red cells in congenital hemolytic jaundice, a fact which fully explains the development and symptoms of the crisis as a result of cessation in the formation of red cells

The findings definitely contradict the theory that an acute increase in the hemolytic process is the reason for the crisis

The crisis should be called *aplastic* and not hemolytic

STUDIES ON THE PANCYTOPENIA OF KALA-AZAR

By CAPTAIN GEORGE E. CARTWRIGHT,* M C , A U S , HUI-LAN CHUNG, M D ,
AND AN CHANG, M D

IT HAS long been recognized that visceral leishmaniasis (kala-azar) is accompanied by marked changes in the peripheral blood, namely, pronounced leukopenia, anemia and thrombocytopenia¹⁻³. Pathologically, the disease is characterized by a marked hyperplasia of the reticulo-endothelial system, particularly of the spleen, liver, bone marrow and lymph nodes. As a result of this reticulo-endothelial hyperplasia there is a marked enlargement of the spleen, and a moderate enlargement of the liver and lymph nodes. The bone marrow is hyperplastic and infiltrated with reticulo-endothelial cells, many of which are parasitized.

The anemia in kala-azar is moderately severe. Kuroya, Young, Tang and Hong⁴ in a study of 151 cases in Kiangsu Province, China, found an average value of 2,930,000 red cells per cu. mm. The lowest count was 700,000. Keefer, Khaw and Yang⁵ in a study of 191 cases in Peiping found the red count in the majority of patients to be between 2 and 4 million per cu. mm. Similar values have been obtained by Young in Peiping,⁶ Botzaris in Greece,⁷ Knowles,⁸ Napier and Sharma,⁹ Bramachari,³ and Rogers¹⁰ in India, and Mo in Manchuria.¹¹ In the majority of patients it has been reported that the hemoglobin is reduced in proportion to the erythrocyte count. Kuroya et al.⁴ reported the mean color index in their 150 cases to be 0.9 with a range of 0.63 to 1.50. Similar results were obtained by Mo.¹¹ Napier and Sharma⁹ have reported a mean of 0.885 in 47 Indian cases. Botzaris⁷ found the color index to be low in 5 cases, normal in 2 and high in 2.

The size of the red cells in kala-azar has not been studied extensively. Napier and Sharma,⁹ using an Eve halometer, report a mean diameter of 7.559μ in 22 cases prior to treatment and a mean diameter of 7.375μ following treatment. Kuroya, Young, Tang and Hong⁴ studied the mean cell diameter in 35 cases. The values varied from 7.03μ to 8.25μ with an average of 7.81μ which they considered normal. In 28.6 per cent of the cases the mean diameters were increased, in 17.2 per cent reduced, and in 54.3 per cent normal. The Price-Jones curves showed a spreading of the base and a flattening of the peak. Curves having a tendency to shift to the right were comparatively numerous. The variation in width of the erythrocyte diameters was 5.2. Therefore, there was an abnormal amount of anisocytosis in most of the cases. There are no reports in the literature concerning mean corpuscular volume or mean corpuscular hemoglobin concentration.

Most authors agree that in kala-azar there is a slight reticulocytosis. In a series of 141 cases⁴ values less than 10 per cent were recorded in 23 cases (16.3 per cent), 11-30 per cent in 39 cases (48.9 per cent), 31-50 per cent in 34 cases (24.1 per

From the Department of Medicine, Chung Ho (Central) Hospital, Peiping, China.

* While on leave, Department of Medicine, University of Utah School of Medicine, Salt Lake City, Utah.

cent), and above 5.1 per cent in 15 cases (10.6 per cent). The mean value in this group was 2.8 per cent. In another series of 47 cases⁹ the mean reticulocyte percentage was reported to be 2.07. Keefer, Khaw and Yang⁵ state in reference to their 191 cases: "The reticulocytes are slightly increased, they are seldom above four per cent."

Normoblasts in the peripheral blood in kala-azar are not a constant or prominent feature. Napier and Sharma⁹ report that in 47 cases with anemia no nucleated red blood cells were observed. Kuroya, Young, Tang and Hong⁴ found normoblasts in the peripheral blood in only 26 of 151 cases examined. In 19 of these the normoblasts numbered 1 to 2 per 100 white cells, in 6 cases 3 to 6 per 100 white cells, while in one case the number reached 19. Keefer, Khaw and Yang⁵ in a study of 191 cases state: "Signs of blood regeneration are usually lacking when one examines the peripheral blood. We have never seen nucleated red blood cells." Several authors have stated that normoblasts frequently appear in the blood but not in great numbers.^{6-8,11} It must be remembered that iron deficiency, a condition in which normoblasts appear in the peripheral blood, may have been a complicating factor in some of the patients.

Polychromatophilia, stippling and poikilocytosis are rarely observed in kala-azar.^{4,7} Polychromatophilia has been reported in 28 out of 151 cases but then only in small numbers.⁴ Stippling was seen in only one case. Knowles⁸ and Botzaris⁷ reported a moderate degree of poikilocytosis but Kuroya et al.⁴ were unable to confirm this.

The characteristic leukopenia in kala-azar was first described by Rogers in 1904.¹⁰ He stated that if the proportion of leukocytes to red corpuscles is less than 1:1500, the patient is probably suffering from kala-azar. Manson-Bahr¹² states that the reduction in the number of leukocytes is persistent and that usually the proportion of leukocytes to red blood corpuscles is reduced to 1:2000-4000. The leukopenia has subsequently been confirmed by many authors.^{4-8,11} Kuroya, Young, Tang and Hong⁴ in their cases found the total leukocyte count below 1000 in 2.7 per cent, 1000-2000 in 21.9 per cent, 2000-3000 in 34.4 per cent, 3000-4000 in 19.2 per cent, 4000-5000 in 13.2 per cent and in only 8.6 per cent was the leukocyte count above 5000. The lowest count was 740 and the highest 11,740. The average leukocyte count was 3052 per cu. mm. This is slightly lower than that reported by Young,⁶ Knowles⁸ and Mo.¹¹

The leukopenia of kala-azar is due mainly to a neutropenia. Both the percentage and the absolute number of neutrophilic leukocytes are markedly reduced. There is a distinct shift to the left as far as the number of juvenile neutrophils is concerned but in one series of 151 cases myelocytes were seen in only one case.⁴ Toxic granules are very few. The eosinophils generally decrease in numbers or disappear entirely from the blood. Basophils occur in normal numbers. Plasma cells are occasionally observed. The percentage of lymphocytes is generally increased to about 50. The absolute number of lymphocytes is moderately reduced. Several authors have reported that both the percentage and the absolute number of monocytes show an increase.⁶⁻⁸ On the other hand, other authors state that the monocytes show an increased percentage, but the absolute count is normal or less than normal.^{10,12}

Kuroya, Young, Tang and Hong⁴ found that the monocytes were less than 10 per cent in 71 per cent of their cases. In only 8.6 per cent was the monocyte count above 15 per cent. Similar findings have been reported by Botzaris.⁷

From the differential white cell studies reported it can be concluded that the characteristic leukopenia of kala-azar is mainly due to the great reduction of neutrophilic leukocytes, the other classes of leukocytes playing only a minor role. Acute agranulocytosis has been reported to occur in patients with kala-azar.^{13, 14}

One of the outstanding clinical features of kala-azar is a hemorrhagic tendency. Epistaxis and bleeding from the mucous membranes are frequent although frank purpura is rare. The hemorrhagic tendency resembles purpura hemorrhagica in that there is a prolonged bleeding time, a normal coagulation time, a nonretractile clot, and in some instances a positive tourniquet test. Darling¹⁵ in 1911 was the first to comment on the change in blood platelets when he stated: "Judging from films from the peripheral blood and spleen, there is a very marked reduction in the number of platelets." In 1930 Yang and Ch'en¹⁶ confirmed Darling's observation. The platelets in their 23 cases varied from 50,000 to 100,000 per cu. mm. Kuroya, Young, Tang and Hong⁴ performed platelet counts on 117 patients. The count was below 40,000 per cu. mm. in 23 per cent, between 40,000 and 80,000 in 42 per cent, between 80,000 and 120,000 in 18 per cent, between 120,000 and 160,000 in 11 per cent, and above 160,000 in 6 per cent with an average for all cases studied of 76,763 per cu. mm.

Detailed studies of the bone marrow in kala-azar with differential cell counts have not been reported. Most of the studies are only gross estimates obtained from postmortem specimens stained with hematoxylin-eosin. These studies for the most part have been made on patients in the advanced stage of the disease. Differential cell studies done on thin smears stained with Wright's stain and taken in the early stages of the disease are lacking. Consequently, there is considerable discrepancy in the literature as to the changes in the marrow. Chatterjee,¹⁷ on the basis of the postmortem femoral bone marrow studies of hematoxylin-eosin preparations in 6 patients, divides the marrow into three stages. In the first and earliest stage a differential count gave the following proportion of cells: myeloid, 23 per cent, erythroid, 25 per cent, clasmatoocytes, 45 per cent, other cells, 7 per cent. About 30 per cent of the clasmatoocytes were parasitized. In the second stage the total number of cells had become fewer and the differential count of one case was as follows: myeloid, 30 per cent, erythroid, 40 per cent, clasmatoocytes, 5 per cent, other cells, 25 per cent. Almost all of the clasmatoocytes were parasitized. In the third, or more advanced stage, the total number of cells had become even fewer, the cells of the myeloid series being diminished. A differential count from one case was as follows: myeloid cells, 11 per cent, erythroid, 50 per cent, clasmatoocytes, 10 per cent, other cells, 29 per cent. Many of the erythropoietic cells, it is stated, were megaloblasts. This finding led the author to state: "The appearance of megaloblasts and a large number of erythroblasts may be associated with the increasing anemia which occurs in this condition and which might ultimately turn into an anemia of the macrocytic type." Piney,¹⁸ on the other hand, states that the erythroid cells are

markedly decreased to less than 8 per cent and that there is a marked increase of the lymphocytes and monocytes in the marrow to about 55 per cent. Meleney¹⁹ studied the rib marrow in one case of kala-azar in man and reported "This marrow contains no fat, and approximately 80 per cent of the space is occupied by clasmatocytes, packed closely together into definite clasmatocyte tissue. The normal hematopoiesis is almost entirely absent, especially erythropoiesis. Most of the cells aside from the clasmatocytes seem to be lymphocytes. There are a few myelocytes and megakaryocytes." Hu,²⁰ in a somewhat more extensive, although still not a detailed study of the bone marrow in human kala-azar, reported similar changes. The marrows were hyperplastic and contained many reticulo-endothelial cells. The number of myelocytes was increased, but the metamyelocytes and leukocytes were either greatly reduced in number or entirely absent. The number of normoblasts was moderately increased in a few cases, but in most instances the number was either normal or decreased. Plasma cells were prominent. The megakaryocytes were reduced from 3 to 4 per high power field to an average of about 2 per high power field. Hu and Cash²¹ studied the bone marrow of two patients coming to autopsy and report "The bone marrow of the femur consisted in a solid mass of firm, dark, grayish red tissue, which microscopically was found to consist mainly of all forms of myeloid cells and nucleated red blood corpuscles. Such a degree of hematopoietic activity is rarely seen other than in cases of pernicious anemia. Many megakaryocytes and a number of large phagocytic cells similar to those seen in the spleen were present."

In hamsters²²⁻²³ and squirrels²⁴ experimentally infected with kala-azar the bone marrow is hyperplastic due to an increase in the number of reticulo-endothelial cells. Chung and Ch'in²⁴ state "In squirrels infected with kala-azar the bone marrow shows the most marked hyperplasia of the reticulo-endothelial cells, as compared with other organs. About three-fourths or more of the marrow space is occupied by these cells. It is true that all of the blood elements of an active marrow are present. But when one considers the preponderance of the reticulo-endothelial cells, one cannot get away from the impression that the myelogenic and erythrogenic elements are actually being crowded out by the reticulo-endothelial cells. In fact, these cells show such an active proliferation that they come to resemble a malignant tumor growth invading or crowding out the marrow tissue." Meleney¹⁹ has reported similar findings in hamsters.

The pathogenesis of the pancytopenia is poorly understood. Most students of the disease have offered the theory,⁴⁻⁵⁻¹¹⁻¹⁹⁻²⁰⁻²²⁻²⁴ and it has been generally accepted, that the hematologic changes are the result of impairment of the hematopoietic function of the bone marrow which is destroyed mechanically by the overgrowth of parasitized reticulo-endothelial cells, that is, myelophthisic anemia. The evidence for this rests solely in the demonstration of numerous reticulo-endothelial cells in the marrow and much of this evidence has been obtained from the animal experiments mentioned above. Napier and Sharma⁹ suggested that the anemia is due to excessive hemolysis. They based their conclusions on the slight reticulocytosis, the presence of an indirect blood Van den Bergh reaction, and the presence of urobilinuria. It has since been suggested that the urobilinuria

is due to hepatic insufficiency ²⁰ Mo¹¹ has pointed out that the erythrocyte fragility is normal. Furthermore, the hemolytic theory does not explain the leukopenia and thrombocytopenia.

It is now recognized that in many conditions in which there is enlargement of the spleen due to hyperplasia of the reticulo-endothelial system there is an accompanying anemia, leukopenia, thrombocytopenia and hyperplasia of the bone marrow ²⁵⁻²⁷ Following splenectomy the cellular elements of the blood and bone marrow rapidly return to normal. These manifestations have been grouped together under the term "hypersplenism." Any one (thrombocytopenic purpura, congenital hemolytic icterus, primary splenic neutropenia) or all (primary splenic pancytopenia) of the cellular elements of the blood may be affected. The pathogenesis of the hematologic changes is in dispute. One group²⁶ holds that a hormonal relation exists between the spleen and the bone marrow. The other²⁵ fosters the "phagocytic hypothesis," in which the anemia, leukopenia and thrombocytopenia are thought to be due to increased phagocytic activities of the enlarged spleen. Since in kala-azar there is marked proliferation of the reticulo-endothelial system and consequent splenomegaly, the possibility that the blood changes are due entirely or at least in part, to hyperfunction of the spleen must be seriously considered. Splenectomy has been reported to be beneficial in kala-azar^{28, 29} but unfortunately the blood changes were not followed closely and the patients received antimony prior to splenectomy. A careful study of the effect of this procedure alone on the blood has not been reported.

MATERIALS

The case material for this study consisted of 143 patients with kala-azar. Twenty-five of these have been previously reported by one of us (H. L. C.)³⁶ All patients gave a history characteristic of the disease. None had received specific therapy prior to study. The diagnosis in each case was proved by the demonstration of *Leishmania donovani* in material from either sternal marrow puncture or splenic puncture. One-hundred and twenty-four cases were uncomplicated.

Twenty-seven patients were studied in detail and this group comprises the main body of this report. All of these except 5 were hospitalized for study. The significant clinical data for this group are presented in table 1. Eighteen of the patients had uncomplicated kala-azar. In general, the majority of these patients were in the intermediate stage of the disease. Follow-up studies after the onset of specific therapy were available in 12 patients.

METHODS

Blood Counts These were performed in the usual manner according to Wintrobe.³⁰

Hemoglobin For these determinations the Sahli hemoglobinometer was used.

Peripheral Blood Smears Smears were prepared by the cover-glass technic³⁰ and stained with Wright's stain. Differential white cell counts were performed on 100 cells, and the morphology of the red cells noted.

Peripheral Platelet Counts The counts were made indirectly by determining the

number of platelets per 1000 red cells in the blood smear. The number of platelets per cu mm of blood was then calculated from the red count which was done at the same time. In normal Chinese we found the platelet count to vary between 288,000 and 384,000 with an average of 330,000 per cu mm.

Globulin Test From an ordinary skin puncture 20 cu mm of blood was taken into a hemoglobin pipet and transferred immediately into a clean test tube (7-8

mm in diameter) containing 0.6 cc of distilled water. The contents of the tube were mixed by whirling in the hand. The tube was then allowed to stand vertically without further shaking and examined at intervals of 5, 15, 30 and 60 minutes. A haziness at the end of 5 minutes was taken to indicate a positive test. A definite settling of the precipitate within 15 minutes was recorded as 4 plus, definite settling of the precipitate within 15 to 30 minutes as 3 plus, definite settling between 30 and 60 minutes as 2 plus, and a haziness with a fine precipitate but no sediment after one hour as one plus.

Spinal Puncture This was performed by the introduction of a large lumbar-puncture needle into the marrow space. A small amount of marrow fluid, usually less than 0.3 cc., was withdrawn into a clean dry syringe and thin cover-glass

FIG. 1. Showing the degree of anemia in 124 patients with uncomplicated kala-azar

FIG. 2. Showing the leukocyte count in 124 patients with uncomplicated kala-azar

preparations drawn and stained with Wright's stain. The cover-glasses were then fixed to glass slides with neutral Canada balsam. After examining three such preparations the percentage of reticulo-endothelial cells was estimated. Because of the tendency of these cells to clump in the thick sections of the preparations and because of their extreme fragility in the thin sections precise counts were not possible. The percentage of these cells parasitized was also estimated. Differential

counts on the bone marrow cells were done on 500 to 1000 cells, exclusive of reticulo-endothelial cells and megakaryocytes, and the percentage of each accurately determined. The total number of megakaryocytes per million nucleated cells was determined by pasting a 10 x 10 mm square cut out of paper over each of three cover-glass preparations. This area represented approximately 8000 oil immersion fields. The number of nucleated cells in each area was estimated by accurately enumerating the nucleated cells, including the reticulo-endothelial

FIG 3 Showing the relation between the duration of symptoms and the hemoglobin (116 patients) leukocyte count (108 patients) and platelet count (36 patients) in uncomplicated kala-azar

cells, in three oil immersion fields in each corner and the center. The megakaryocytes in each of the three 10 x 10 mm squares were counted and the number per million nucleated cells calculated and averaged. To determine the percentage of megakaryocytes forming platelets at least 50 megakaryocytes were counted.

The values for the relative numbers of nucleated cells in the normal bone marrow were taken from Wintrobe.³⁰ These values agree closely with those found by us in normal marrow. The total number of megakaryocytes per million nucleated cells was determined in 10 normal marrows. The values were found to range from 85 to 200 with an average of 142. The percentage of megakaryocytes forming platelets in normal marrow was found to vary from 55 to 87. The average percentage was 75.

In attempting to interpret the correlation between the duration of the symptoms and the blood counts (fig 3), the size of the spleen and the blood counts (fig 4)

FIG 4 Showing the relation between the size of the spleen and the hemoglobin (117 patients), leukocyte count (117 patients) and platelet count (36 patients) in uncomplicated kala-azar

FIG 5 Showing the relation of the size of the spleen and the duration of symptoms

and the duration of symptoms and the size of the spleen (fig 5) certain considerations must be kept in mind. Many patients were unable to remember clearly the exact time of onset of symptoms. The size of the spleen was measured in one diameter only and the size of the spleen in relation to the size of the patient was not considered. Characteristic of kala-azar are remissions and relapses rather than

a gradually progressive course. The curves are plotted from a large body of data. They are shown to represent the general trend. A particular patient might not be expected to fit exactly in this scheme.

OBSERVATIONS

A PERIPHERAL BLOOD

1 *Anemia* The distribution of the hemoglobin values in 124 uncomplicated cases is shown in figure 1. The average value for the entire group was 8.3 grams per cent. The anemia at times was severe. In 33 per cent of the patients the hemoglobin was less than 7 grams per cent. As shown in figure 3, significant anemia (10.6 Gm. per cent) was usually present shortly after the onset of symptoms and was thereafter gradually progressive, reaching an average value of about 5 grams per cent in 24 months if the disease remained untreated. In patients with kala-azar and an associated bacterial infection the anemia was more severe (average for 19 patients, 7.2 grams per cent). The correlation between the size of the spleen and the degree of anemia is demonstrated in figure 4. By the time the spleen had become palpable there was a significant degree of anemia (11.2 Gm. per cent hemoglobin) and thereafter the anemia increased in proportion to the splenic enlargement.

2 *Red Cell Morphology* The red cell morphology was studied in 27 cases (table 2). Facilities were not available for determining the mean corpuscular volume. Judging from the appearance of the red cells in the thin smears the anemia was normocytic. The average color index for the group was 1.0. A significant degree of macrocytosis was observed in only two smears and complications were present in both patients. Neither microcytosis nor hypochromia were observed. A moderate amount of anisocytosis was generally present but poikilocytosis of significant degree was observed in only 4 of the uncomplicated cases. Polychromatophilia and stippling were not seen in uncomplicated kala-azar whereas a significant degree of polychromatophilia was seen in 3 of the 9 patients with complications. Nucleated red cells were observed in the peripheral blood in only 5 of the 27 patients and then never in large numbers. Three of the 5 patients with nucleated red cells in the peripheral blood presented complications.

3 *Leukopenia* As demonstrated in table 2 and figure 2, leukopenia was an almost constant feature of uncomplicated kala-azar. The average white cell count for the group of 124 patients was 2835 per cu. mm. The highest white count observed was 7250. Only 16 of the patients (12.9 per cent) had a white count above 5000 per cu. mm., all of these being early cases. Leukopenia was invariably present in late uncomplicated kala-azar. The leukopenia developed early, about the time of the onset of symptoms, and thereafter became only slightly more severe (fig. 3). The reduction in the white count appears to correspond closely to the degree of splenic enlargement (fig. 4). Leukopenia was usually present at the time the spleen was first palpable.

The white count in the patients with bacterial infections in addition to kala-azar was variable (table 2). Leukopenia was present in 4, a normal leukocyte count in 3 and a leukocytosis in 2. The latter response is demonstrated in figure 6.

Following treatment of the severe noma with penicillin the white count fell from 18,000 to 4000 per cu mm and after specific antileishmanial therapy returned to 6200

* N—Normocytic, M—Macrocytic

4 *Differential Leukocyte Count* The most conspicuous change in the differential count was a reduction in the neutrophils (table 2.) In uncomplicated cases the neutrophils were reduced to an average of 32.7 per cent. This was a reduction in the absolute number from about 4000 to 910 per cu mm. A significant "shift" of the nuclei, either to the left or to the right, was not noted. The proportion of

metamyelocytes was not increased significantly and the absolute number was reduced by less than one-half. A single myelocyte was seen in two smears. Toxic granules in the neutrophils were not evident. Plasma cells were occasionally seen. Although the percentage of lymphocytes was increased to an average of 52.1 per cent, the absolute number of lymphocytes was reduced from the normal of about 2100 to 1450 per cu mm. The percentage of monocytes was slightly above normal but again the absolute number was reduced (2.45 per cu mm average). Eosinophils were seen in only 3 smears and then not above 2 per cent. Basophils were also rarely seen.

5. *Platelets* The platelet count in the majority of the patients was reduced (table 2). In the uncomplicated cases the average platelet count was 103,000 per cu mm, as compared with the normal average value of 330,000 per cu mm obtained by us under the conditions of this study. As seen in figure 3 the thrombocytopenia developed somewhat later than the anemia and leukopenia. Significant thrombocytopenia was generally not present until about two months following the onset of symptoms. After this time the platelet count fell rapidly. As the spleen enlarged the platelet count became progressively lower (fig. 4). A prolongation of the bleeding time and in most cases a positive tourniquet test were associated with the thrombocytopenia, although frank purpura was present in only one of the 143 patients. When complicating infections were present the thrombocytopenia was generally more severe. In one patient (no. 21), critically ill with lobar pneumonia, the platelet count was reduced to 51,000 per cu mm and the bleeding time was increased to 30 minutes. Another patient (no. 13), with severe noma, had a platelet count of only 34,000 and a bleeding time of seven minutes. However, in one patient with complicating diphtheria the platelet count was 306,000 per cu mm even though symptoms of kala-azar had been present for six months.

B BONE MARROW

1. *Hyperplasia* The bone marrow in kala-azar was consistently hyperplastic. Thin smears and imprints of sternal marrow were exceedingly cellular. Globules of fat were rarely seen. Indeed it was even difficult to obtain a thin smear because of the cellularity of the marrow. Biopsy specimens of the sternal marrow stained with hematoxylin-eosin contained little fat and showed hyperplasia of the reticulo-endothelial tissue as well as blood forming tissue.

2. *Reticulo-endothelial Cells* Much of the hyperplasia in the sternal marrow could be accounted for by the increase in reticulo-endothelial cells. These cells, it was estimated, constituted from 5 to 50 per cent of all the cells in the sternal marrow (table 3). In about half the cases less than 1 per cent of the reticulo-endothelial cells were parasitized but in one patient (no. 20) as many as 60 per cent were estimated to be parasitized. Even in the marrows with 40 to 50 per cent reticulo-endothelial cells, large numbers of bone marrow cells were present. In no case did there appear to be growth of reticulo-endothelial cells at the expense of the normal blood forming tissue. There was a tendency for the proportion of reticulo-endothelial cells to increase with the duration of the disease but there was a very poor correlation between the proportion of these cells and the severity

of the anemia, leukopenia and thrombocytopenia. Leukopenia appears to precede any great growth of reticulo-endothelial cells in the marrow (patients nos. 4,

— Less than

11, 12, 21, 26) Photomicrographs of parasitized reticulo-endothelial cells are presented in figure 7

3 *Leukocytes* The most striking alteration of the leukocytes was in the polymorphonuclear neutrophils. These cells were reduced to less than 8 per cent from the normal of about 20 per cent. This reduction appeared to take place early. The

average value for the 6 uncomplicated cases of approximately one month's duration was 6.4 per cent whereas the average value for the group was 5.4 per cent. This diminution in the adult neutrophils appears to be the first change to take place in the bone marrow. This coincides with the finding of leukopenia in the peripheral blood early in the course of the disease. The percentage of myeloblasts, promyelocytes, neutrophilic myelocytes and metamyelocytes was not significantly altered in most patients, although the metamyelocytes as well as the adult neutrophils were

FIG. 6 Patient (no. 18) with kala-azar and severe noma associated with leukocytosis and neutrophilia. Note the development of leukopenia and neutropenia following treatment of the noma with penicillin (1.25 million units intramuscularly) and the return to normal with specific antileishmanial therapy.

markedly diminished in the one case of extremely long duration (no. 25). The eosinophilic myelocytes and adult eosinophils were reduced in numbers, especially in the late cases where they were rarely if at all encountered during the examination of 500 to 1000 cells. Basophilic cells were more infrequently seen than normally. Lymphocytes and monocytes were present in normal numbers. The granulocyte-nongranulocyte ratio was reduced from approximately 5:1 to 1:6. The proportion of plasma cells was increased from 0.4 per cent to an average of 2.8 per cent.

4. *Erythroid Cells* Erythroid cells were numerous in the bone marrow in kala-azar, constituting about 36 per cent (normal, 22 per cent) of all cells, exclusive of

FIG 7 Showing parasitized reticulo-endothelial cells in the sternal marrow

FIG 8 Showing the reduction in the myeloid (leukocyte)-erythroid ratio with progressive enlargement of the spleen

reticulo-endothelial cells The majority of nucleated red cells were polychromatic normoblasts Megaloblasts were not encountered and there was no increase in early forms of nucleated red cells The leukocyte-erythroid ratio was shifted from the normal of approximately 3.5 : 1 to an average of 1.8 : 1 (table 3) This ratio decreased as the size of the spleen increased, as shown in figure 8 The granulocyte-erythroid ratio was diminished from 3 : 1 to 1.2 : 1

FIG 9 Typical megakaryocytes from the bone marrow in untreated kala-azar Note the absence of platelet formation around the periphery of the cytoplasm of the cells

5 *Megakaryocytes* The relative number of megakaryocytes in the sternal marrow of the uncomplicated cases varied considerably The number was less than normal in 6, normal in 11 and slightly greater than normal in one The number of megakaryocytes per million nucleated cells (including reticulo-endothelial cells) for the entire group of uncomplicated cases averaged 122, as compared with the normal of 142 In view of the fact that the reticulo-endothelial cells were increased in numbers, the ratio of megakaryocytes to nucleated blood forming cells was somewhat higher The relative number of megakaryocytes in the 9

patients complicated by other diseases was less than normal in 8 and normal in only one

Staining abnormalities were noted in many of the adult megakaryocytes. Their cytoplasm was less granular and took on a purplish hue. The nuclei of many of these cells appeared somewhat degenerated. No striking abnormalities were noted in the differential counts of the megakaryocytes although this was

FIG. 10. Typical megakaryocytes from normal sternal marrow. Note the moderate platelet formation around the periphery of the cells.

not studied in detail. All forms from megakaryoblasts through adult megakaryocytes were present. The latter were more frequently seen than any other form.

Platelet production from the megakaryocytes was found to be markedly reduced. In normal marrow approximately 75 per cent (55 to 87) of the megakaryocytes were found to contain platelets or platelet-like bodies at the peripheries of their cytoplasm, whereas in kala-azar platelet production was obvious in only about 32 per cent and then never to any great extent (fig. 9). In normal marrow as many as 60 or more platelets could be seen attached to the periphery of the cytoplasm of

the megakaryocytes and it was not unusual to find between 10 and 50 (fig 10). In the kala-azar marrows there generally were less than 10 platelets surrounding the relatively few platelet-producing megakaryocytes. In only 4 of the marrows was platelet production from megakaryocytes normal and all of these were ex-

tremely early cases (nos 9, 11, 23, 27) Free platelets were scarce in the bone marrow preparations. Large groups of platelets, such as are noted in normal marrow, were almost never seen.

6 *Changes in the Sternal Marrow During Therapy* Follow-up studies were available in 12 patients under treatment. These studies are presented in table 4. Due to

existing circumstances a variety of antileishmanial drugs, American, German, British, and Japanese, was used. Some of these were more efficacious than others. The response of 8 of the patients (nos. 4-6, 9, 13-15, 18) was good, in 4 (nos. 7, 8, 16, 20) the response was poor. The changes in the peripheral blood of one patient (no. 18) during treatment are presented in figure 6.

During effective therapy parasitized reticulo-endothelial cells rapidly disappeared and the percentage of reticulo-endothelial cells gradually diminished. There was a "shift" of the leukocytes of the bone marrow to the right. The proportion of neutrophilic myelocytes diminished and the polymorphonuclear neutrophils increased. The metamyelocytes temporarily increased, decreased or remained unchanged. At the same time there was a significant increase in eosinophilic myelocytes and adult eosinophils. Basophilic myelocytes were more frequently seen. Lymphocytes became more numerous. The relative number of plasma cells diminished to normal. Nucleated red cells became less numerous as the leukocyte-erythroid ratio increased to normal. As this change took place the proportion of polychromatic normoblasts to orthochromatic normoblasts decreased from 2.9 to 0.7. These changes are shown graphically in figure 11.

The number of megakaryocytes per million nucleated cells increased during effective therapy. The only exception to this was patient no. 6. In this patient the number of megakaryocytes per million nucleated cells was slightly greater than normal before therapy and the number decreased to within the normal range during therapy.

The percentage of megakaryocytes forming platelets increased to within the normal range in 6 of the 8 patients responding to therapy (table 4). Not only did the percentage of megakaryocytes forming platelets increase but the average number of platelets attached to each megakaryocyte was greatly increased, even beyond the normal. This is illustrated in figure 12. The number of platelets attached to each of 100 megakaryocytes in the marrow of the same patient (no. 6) was counted as accurately as possible before and after treatment and compared with a normal.

Photomicrographs of megakaryocytes taken from the same preparations as used in preparing figure 12 are presented in figures 9, 10, and 13. These photographs again illustrate the absence of platelet formation in untreated kala-azar (fig. 9) and the greatly increased platelet formation in the marrow following treatment (fig. 13) as compared with the normal (fig. 10).

Following the production of platelets by the megakaryocytes, huge groups of platelets were frequently seen in the marrow smears. These were larger and more numerous than those seen in smears made from normal marrow and were in sharp contrast to the very few platelets seen scattered about the marrow in the preparations made from untreated cases. The platelet count in the peripheral blood then approached normal as a rule, although no increase was noted in patients 13 and 15. However, the platelet counts were just at the lower limit of normal and it would be expected that the platelet rise in the peripheral blood would occur later than the bone marrow change.

Two patients (nos. 14, 18), in whom there was no increase in platelet production

FIG 11 Bone marrow changes in a patient (no 14) with kala-azar before and during specific anti-leishmanial therapy (solunesbosan)

FIG 12 Number of platelets attached to the cytoplasm of 100 megakaryocytes in normal marrow, in a patient (no 16) with kala-azar prior to specific therapy and in the same patient after specific therapy

in the bone marrow, were both complicated in that severe infections existed. As expected, no rise in the platelets in the peripheral blood was noted.

From table 4 it is evident that the first change which took place in the platelet forming tissue was an increase in the number of megakaryocytes. Following this,

FIG. 13. Typical megakaryocytes from the bone marrow of a patient with kala-azar following specific therapy. These photomicrographs were taken from a preparation of sternal marrow taken from the same patient (no. 6) as were those in figure 9. Note the large number of platelets at the periphery of the cells. Platelet production from the megakaryocytes increased and later there was a rise in the number of platelets in the peripheral blood. This took place after there had

been a significant rise in the number of leukocytes and the quantity of hemoglobin in the blood. Thus the three cellular elements of the blood were restored to normal in the same order as their reductions from normal had taken place. The increase in platelets in the peripheral blood was not as dramatically rapid as occurs following splenectomy in primary thrombocytopenic purpura. This is natural since the reduction in the size of the spleen in kala-azar in response to therapy is very gradual over the course of months.

Four patients (nos 7, 8, 16, 20) responded poorly to therapy (table 4). There was no detectable clinical improvement, no diminution in the size of the spleen, and little or no change in the peripheral blood. *Leishmania* were present in the bone marrows twenty-nine days after treatment was commenced in one patient (no 20), after thirty-seven days in another (no 16) and after seventy days in another (no 8). *Leishmania* were found in the spleen in the last named patient on the one hundredth day of therapy. The marrows remained normoblastic and a 'shift' to the right in the myeloid series did not occur. There was, however, an increase in the number of megakaryocytes per million nucleated cells in each case and in 2 of the patients (nos 7, 20) platelet production by the megakaryocytes had commenced. Three of the patients (nos 7, 8, 16) were treated initially with a Japanese preparation, solunesbosan. Two of the patients (nos 16, 20) had complicating infections and 2 (nos 8, 16) developed agranulocytosis during therapy. All 4 of these patients were heavily parasitized at the onset of therapy and none were in the early stage of the disease. Patient no 20 was given 50 mg of pteroylglutamic acid orally daily for 10 days without any apparent effect on the leukopenia.

DISCUSSION

Differential counts on the sternal marrow from cases of kala-azar have thus revealed a rather characteristic pattern. Myeloblasts, promyelocytes, neutrophilic myelocytes and metamyelocytes were present in approximately normal proportions but polymorphonuclear neutrophils were markedly reduced and eosinophilic cells were rarely seen. In the patient with disease of two years duration, the metamyelocytes were also reduced in number and in one patient with kala-azar and advanced bilateral pulmonary tuberculosis approximately 62 per cent of the myeloid cells were myelocytes or younger forms even though the leucocyte-erythroid ratio was 18:1. This would seem to indicate either an inability of the leucocytes to mature fully or rapid dissolution of the adult cells. Study of the bone marrow has shown, however, that this defect can, under certain circumstances, be overcome since occasionally patients with secondary bacterial infections develop leucocytosis in spite of the existence of severe kala-azar with marked granulocytopenia.

The presence of staining abnormalities, the reduction in total numbers of megakaryocytes in some cases, and the absence of a normal degree of platelet production suggest an abnormality in the development of the megakaryocytes which results in a failure to produce platelets. This offers an explanation for the thrombocytopenia seen in kala-azar. If platelets were being destroyed rapidly in the peripheral blood one would expect to find hypertrophy of the megakaryocytic

tissue in the marrow with each megakaryocyte producing a maximal number of platelets

Nucleated red cells, especially polychromatophilic normoblasts were numerous in the marrow. It is impossible to say from our data whether the increase was absolute or only relative to a decrease in the leucocytic tissue. One might postulate that since there are many normoblasts in the marrow there is a failure of these cells to make the transition to erythrocytes. Such a situation does exist in the bone marrow in patients with anemia due to iron deficiency and in patients with disturbed hemoglobin synthesis due to lead intoxication. On the other hand, it is also true that in patients with active erythropoiesis, such as occurs in anemia due to hemorrhage or hemolysis, there is an increase in normoblastic activity in the marrow.

None of our patients were jaundiced. Rachmilewitz, Braun and De Vries³⁸ have reported a single patient with kala-azar, macrocytic anemia, reticulocytosis, normoblastic bone marrow, jaundice and a significantly increased excretion of urobilinogen in the urine and feces. They state "The type of anemia, the hyperplastic bone marrow, the increased excretion of urobilinogen before treatment, and the subsequent changes following treatment strongly suggest increased red cell destruction (most probably by phagocytosis) as the cause of the anemia." From our studies we cannot rule out this possibility but it should be noted that patients with chronic liver disease (cirrhosis) and jaundice may have an increased excretion of both urinary and fecal urobilinogen in the absence of increased hemolysis.³⁹ The fact that the patient reported by Rachmilewitz, Braun and De Vries had macrocytic anemia and jaundice suggests that their patient varied somewhat from the usual patient with kala-azar.

As pointed out in the introduction it has been generally accepted that the hematologic changes seen in kala-azar are the result of impairment of the hemopoietic function of the bone marrow which is destroyed mechanically by the overgrowth of parasitized reticulo-endothelial cells, that is, the anemia is classed with the myelophthisic or leuko-erythroblastic anemias. However, the hematologic changes in kala-azar differ in several respects from those seen in patients with carcinomatosis, osteosclerosis, multiple myeloma, myelosclerosis and marble bone disease. In such examples of so-called "myelophthisic anemia" the most significant abnormality of the erythrocyte series in the peripheral blood is the presence of nucleated red cells in numbers quite out of proportion to the degree of anemia.³⁰⁻³⁵ As many as 53 nucleated red cells per 100 leucocytes have been observed in cases in which there was little anemia.³⁰ Polychromatophilia and stippling are frequently seen. Myelocytes in the peripheral blood are almost a constant feature.^{31, 32} and myeloblasts are occasionally seen. The leukocyte count is usually normal, occasionally increased, and only rarely reduced and the differential white cell formula usually maintains its normal proportions.³⁰⁻³⁵ In kala-azar nucleated red cells are rarely seen in the peripheral blood. In our own series of patients they were seen in only 5 patients and then in small numbers. Napier and Sharma⁹ and Keefer, Khaw and Yang⁵ did not observe nucleated red cells in the peripheral blood of any of their patients even when severe anemia was present.

Kuroya et al.⁴ recognized normoblasts in only 17 per cent of their cases and then never in very great numbers. Polychromatophilia and stippling are also rarely seen. A single myelocyte was seen in two smears in the series reported here. Kuroya et al.⁴ observed myelocytes in only one case out of 151. In uncomplicated kala-azar there is almost invariably a leukopenia. In the differential white cell formula in kala-azar the lymphocytes, in contrast to what occurs in myelophthisic anemia, predominate.

Vaughan^{32, 36} has reported that leuko-erythroblastic anemia (myelophthisic anemia) is associated with an increase rather than a decrease of skeletal red marrow and is not dependent upon mechanical limitation of the marrow. She was able to find little correlation between the degree of mechanical blocking and the degree of anemia. In some of her cases with great degrees of occlusion of the marrow there was little anemia. In the series of patients presented in this study infiltration of the sternal marrow by reticulo-endothelial cells varied from 5 to 50 per cent and there was little correlation between the degree of infiltration and the severity of the blood changes. Leukopenia frequently appeared before there was significant infiltration of the marrow. This has also been observed by others.^{24, 26} Furthermore, evidence of an extension of the functioning bone marrow in kala-azar has been observed repeatedly.^{11, 19, 20} In normal adults only approximately half of the marrow is in an active state. Thus, if all of the marrow is made available and if 50 per cent of this is invaded by reticulo-endothelial cells there may still be no reduction from the normal in the total amount of functioning tissue.

The hematologic changes in kala-azar are similar in many respects to those seen in Gaucher's disease, Still-Chauffard-Felty syndrome, tuberculous splenomegaly and 'primary splenic pancytopenia'.³⁰ In these so-called "hypersplenic states" there is anemia with little evidence of blood regeneration, neutropenia with a relative lymphocytosis and thrombocytopenia. Hirschboeck²⁷ has reported differential counts of sternal marrow smears in two cases of Still-Chauffard-Felty syndrome. In both cases the marrow was hyperplastic and normoblastic. There was a marked shift to the left of the myeloid elements and the majority of the cells were myelocytes and metamyelocytes. Similar findings have been reported by Doan and Wright²⁶ in 3 cases of 'splenic pancytopenia'. In 2 of these cases the myeloid-erythroid ratio was reversed, 1:4. In Banti's syndrome and in other splenomegalic states Limarzi and his co-workers³⁷ have reported myeloid hyperplasia in the earliest stage and "maturation arrest" of the myeloid and megakaryocyte tissue later. In the last stage of the condition marked erythroid immaturity was found as well.

In kala-azar the reduction in the numbers of erythrocytes, leukocytes and platelets is, in general, proportional to the degree of splenic enlargement.

One apparent point of difference between the bone marrow in kala-azar and that in symptomatic 'hypersplenic' thrombocytopenic purpura is that Dameshek and Miller²⁶ in 5 cases of the latter (Gaucher's disease, infectious splenomegaly, cirrhosis of liver, splenic vein thrombosis, and Felty's syndrome) found the number of megakaryocytes increased and a normal proportion of platelet-producing cells. Their results in this group of cases differed from their findings in idiopathic

thrombocytopenic purpura (which they consider a form of hypersplenism) in that the proportion of platelet producing cells was markedly reduced in the idiopathic group *

Although there is, thus, a certain amount of evidence suggesting that the blood changes associated with kala-azar are due to hyperfunction of the spleen, it is clear that no direct evidence has been given in this paper for the hypersplenic theory. Such evidence could come from the demonstration that the anemia, leukopenia and thrombocytopenia are alleviated by splenectomy †. This was considered but for various reasons was not performed. Experiments with splenectomy are now under way in animals experimentally infected with kala-azar and it is anticipated that this will be the subject of another communication ‡.

SUMMARY

1. The peripheral blood changes in uncomplicated kala-azar are those of pancytopenia, namely, anemia, leukopenia and thrombocytopenia. The red blood cell morphology is normal and there is very little evidence of increased erythrocytic activity. The leukopenia is due to a reduction in all types of cells, especially neutrophils.

2. When the disease is complicated by other infections the anemia is more severe and anisocytosis, poikilocytosis, and polychromatophilia may appear and normoblasts may occasionally be seen in the peripheral blood. Leukocytosis may develop, the leukopenia may persist or the syndrome of agranulocytosis may intervene.

3. As the duration of the disease increases, the spleen tends to become larger and the anemia, leukopenia and thrombocytopenia become progressively more severe. Leukopenia generally appears first, followed by anemia and finally thrombocytopenia. The degree of leukopenia, anemia and thrombocytopenia follow closely the degree of splenic enlargement.

4. The bone marrow in kala-azar is hyperplastic and infiltrated by reticulo-endothelial cells. In spite of this there appears to be an abundance of blood forming tissue, especially erythropoietic tissue.

5. Differential cell studies on preparations of sternal marrow reveal a marked

* More recent studies by Dameshek and Estren indicate a very definite diminution in platelet production by megakaryocytes in various types of hypersplenism, both due to known cause (i.e. symptomatic or secondary) and in idiopathic cases, the findings being similar to those in idiopathic thrombocytopenic purpura. *Ed*

† Since this paper was submitted for publication a report has appeared by Burchenal, Powers and Haedicke (*Am J Trop Med* 27: 699, 1947) of a case of leishmaniasis with severe anemia and leukopenia which was refractory to antileishmanial therapy. Following splenectomy there was a rapid and sustained increase in leukocytes and hemoglobin. Reference is made in this paper to two other case reports of leishmaniasis in the literature in which splenectomy was followed by a rapid rise in leukocytes.

‡ Preliminary results indicate that hamsters experimentally infected with *Leishmania donovani* develop a leukopenia (5,625 cu. mm.) as compared with normal noninfected hamster (10,625 cu. mm.). Two months following splenectomy the leukocyte count had risen to 14,437 cu. mm. in the infected group, whereas there was only a slight increase (12,475 cu. mm.) in the normal noninfected group following splenectomy.

reduction in the polymorphonuclear neutrophils and eosinophils Myeloblasts, promyelocytes, neutrophilic myelocytes and metamyelocytes are present in approximately normal proportions as are the lymphocytes and monocytes Plasma cells are somewhat increased Erythroid cells, especially polychromatic normoblasts are numerous and the leukocyte-erythroid ratio is altered, more than the normal proportion of normoblasts being found Megakaryocytes are present in normal or slightly reduced numbers Staining abnormalities are noted in these cells and there is a striking reduction in platelet production

6 During effective anti-leishmanial therapy parasitized reticulo-endothelial cells disappear and the percentage of reticulo-endothelial cells gradually diminishes as the polymorphonuclear neutrophils increase There is a significant increase in the eosinophilic cells Lymphocytes become more numerous and the plasma cells diminish in number Nucleated red cells become less numerous and the leukocyte-erythroid ratio returns to normal At the same time the proportion of orthochromatic normoblasts to polychromatic normoblasts increases The relative number of megakaryocytes increases and platelet formation from the megakaryocytes is accelerated even beyond the normal Huge groups of platelets are frequently seen in the marrow smears A rise in platelets in the peripheral blood takes place late, after there has been a significant rise in hemoglobin and leukocytes The three cellular elements are restored to normal in the peripheral blood in the same order as their reduction from normal

7 Evidence is presented which contradicts the view that the pancytopenia is due to a crowding out of the bone marrow by reticulo-endothelial cells

8 Certain similarities between the hematologic changes in this disease and those accompanying the hypersplenic syndromes are noted

THE EFFECTS OF ESTROGENS ON THE BONE MARROW OF ADULT FEMALE DOGS

By ROGER C. CRAIGS, M.D.*

ESTROGENS have been found to have profound effects on the hemopoietic system of dogs¹⁻¹⁴. Large doses of natural or synthetic estrogens produced hemorrhagic purpura, gradual anemia, and a profound leucocytosis which was followed by a leucopenia. Differential counts showed that the neutrophils were the cells responding to the injections, and Arneeth counts showed a swing to the left followed by a corresponding shift to the right. These injections also produced a slight liver damage. Although the time required to produce death varied with each animal, a daily dose of 50 mg. of estrogen ultimately killed the dog.

Except for the work of Arnold and his co-workers, little attention has been given changes in the bone marrow as a result of estrogen injections. Accordingly, this experiment was performed to describe the changes produced by estrogens in the bone marrow of adult female dogs.

METHODS

Adult female dogs of 8-12 kilograms body weight were used in this study.

Each dog was trained to stay on the dog board and blood was removed from femoral vessels without anesthesia. Erythrocyte and white cell counts were made with U.S. certified pipets and the improved Neubauer counting chamber. Smears were made with the two-coverglass technic and differential counts were made on 200 cells. Hemoglobin determinations were made with a Hellige hemometer.

Bone marrows were studied in the following manner. The whole femur was removed at autopsy. A single 1½ inch piece was removed at the proximal end of the femur, the proximal cut being made with a saw just distal to the trochanters. The piece of bone was then split lengthwise with bone forceps and the top half of the bone removed leaving the bone marrow intact in a "boat" of bone. This was then placed in Helly's fixative. The bone marrow was removed from the "boat" of bone after it had become firm in the alcohols. After embedding in paraffin, it was sectioned at 6 micra and stained with toluidin blue and eosin. Differential counts were made on 500 cells.

All injections were given intramuscularly and in sesame oil.

RESULTS

Several blood examinations were performed on each dog before estrogen therapy was given. The average blood figures obtained from 45 separate blood samples from 14 dogs are summarized in table 1.

From the Department of Anatomy, Boston University School of Medicine, Boston, Mass.

This work was done with the aid of a grant from the Committee on Research in Endocrinology of the National Research Council.

* With the technical assistance of Miss Betsy Nadell and Mr. Salvatore Lunetta.

Figure 1 shows a typical curve for the total white cell count of an adult dog under estrogen treatment. The height of the curve varied with each animal and some dogs exhibited a second curve but the terminal effects were the same. Each dog was autopsied when the leucocyte count was at a level indicated in figure 1.

TABLE I—Normal blood figures for adult female dogs taken from 45 separate blood samples from 14 dogs \pm = standard deviation

Erythrocyte count in millions per cu. mm	6.55 \pm 0.73
Hemoglobin in Gm. per 100 cc	14.8 \pm 2.1
Leucocyte count in millions per cu. mm	13.2 \pm 4.8
Neutrophils in per cent	69.6 \pm 9.1
Eosinophils in per cent	4.2 \pm 1.6
Basophils in per cent	0.1 \pm 0.21
Lymphocytes in per cent	19.7 \pm 8.6
Monocytes in per cent	2.8 \pm 2.2

FIG. 1. Showing a typical leucocyte response of adult dogs to injections of large doses of estrogen. The dogs described in this paper were autopsied when the total white counts were as indicated.

This gives a progressive story of the changes produced in the bone marrow during treatment with estrogens.

Dogs No. 12 and No. 26. These 2 animals served as controls and were autopsied after no treatment. The bone marrows of the 2 dogs were similar in appearance (figure 2). The myeloid elements were more concentrated toward the periphery and the marrow gave the appearance of a normal distribution of cellular elements.

Differential counts showed that 40.4 per cent of the cells were erythroid in nature and 43.7 per cent of the cells were neutrophilic elements. Further details are given in table 2.

These counts differ slightly from counts reported by other workers. Alexandrov¹⁵ reported 23.4 per cent erythroid elements and 43.0 per cent neutrophilic elements, Stasney and Higgins¹⁶ found 59.0 per cent and 24.2 per cent respectively, Mulligan¹⁷ reported 40.1 per cent erythroid and 50.1 per cent neutrophilic, and Meyer and

FIG. 2. Bone marrow of a normal control dog. Note the normal distribution of myeloid elements.

Bloom¹⁸ have found erythroid elements to be 38.7 per cent of the bone marrow cells and neutrophilic elements to be 45.7 per cent of marrow cells. These four groups of workers used the sternum, rib, rib, and ilium respectively as a source for marrow while the present work utilized the femur. Stasney and Higgins,¹⁶ however, found that the source of the bone marrow made little difference as far as the distribution of the cells was concerned.

Dog No. 14. This animal was autopsied after twenty-five days of treatment with a total of 89.0 mg. of stilbestrol. * The leucocyte count was close to the peak of rise, having increased from 10.5 thousand cells

* I am greatly indebted to Dr. C. F. Church of the Squibb Institute for Medical Research for the stilbestrol used in this experiment.

TABLE 2 — *Differential counts on bone marrows of adult female dogs treated with estrogen*
Cells rarely found have not been included

Dog	Total leucocyte count in thousands per cu mm	Erythroid elements	Neutrophilic elements	Eosinophilic elements	Promyelocytes	Hemocy toblasts
Normal controls	13 2	%	%	%	%	%
# 14	46 0	40 4	43 7	7 0	3 8	4 7
# 9	21 1	3 6	90 0	0 4	2 6	3 4
# 11	18 8	7 6	86 4	1 4	1 2	3 0
# 16	1 2	31 4	64 8	0 2	0 0	3 2
# 2	0 8	97 4	0 6	0 6	0 0	1 0
# 1	0 2	96 5	0 0	0 5	0 0	3 0
		Not enough cells to count				

FIG 3 Bone marrow of dog No 14 autopsied when the total white cell count was near its maximum response. Note the large masses of neutrophilic elements
 per cu mm to 57 0 thousand cells, and then decreased to 46 0 thousand cells per cu mm at the time of autopsy. The erythrocyte count was 7 34 million cells per cu mm, hemoglobin, 18 5 Gm per 100 cc

EFFECTS OF ESTROGENS ON BONE MARROW OF DOGS

neutrophils, 91.0 per cent, eosinophils, 2.0 per cent, basophils, 1.0 per cent, lymphocytes, 5.5 per cent, and monocytes, 0.5 per cent

Although erythroid elements were present, the bone marrow appeared to be almost completely composed of neutrophilic elements (figure 3). Differential counts (table 2, No. 14) revealed that neutrophilic elements represented 90.0 per cent of the cells in the bone marrow while the erythroid elements showed a relative decrease to only 3.6 per cent of marrow cells (normal dogs 43.7 per cent neutrophilic elements, 40.4 per cent erythroid elements)

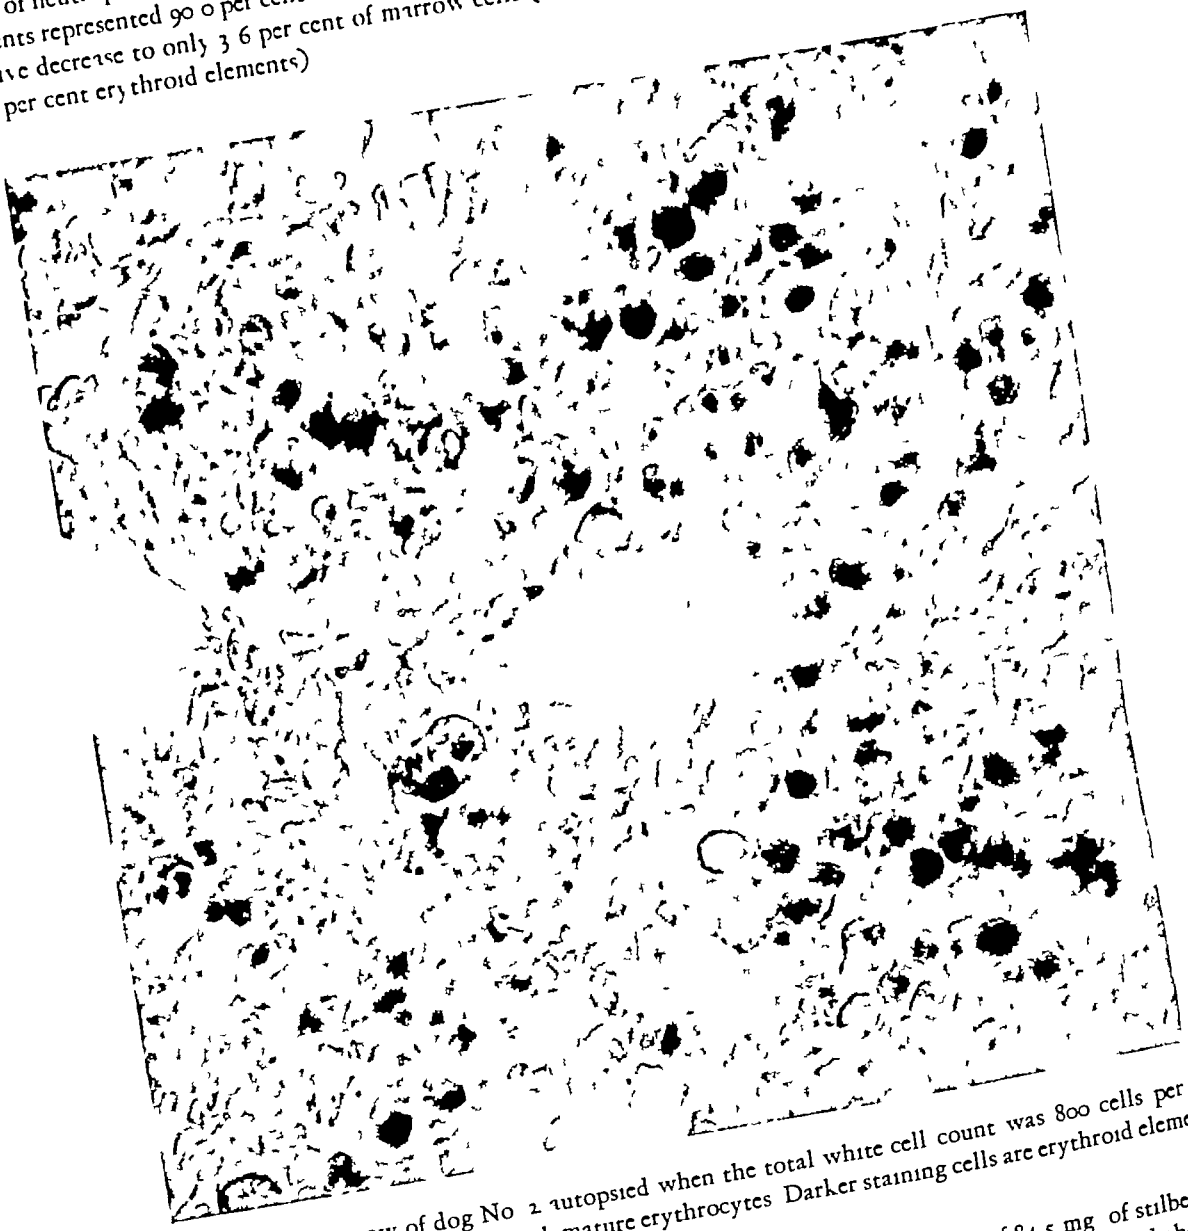

FIG. 4 Bone marrow of dog No. 2 autopsied when the total white cell count was 800 cells per cu mm. Note the extreme congestion with mature erythrocytes. Darker staining cells are erythroid elements.

Dog No. 9 This animal was treated for twenty-seven days with a total dose of 84.5 mg of stilbestrol. The leucocyte count increased from 11.7 thousand cells per cu mm to 36.8 thousand cells, and then decreased to 21.1 thousand, at which time it was sacrificed. At autopsy, the erythrocyte count was 5.88 million cells per cu mm, hemoglobin, 14.5 Gm per 100 cc, neutrophils, 89.0 per cent, eosinophils, 0.5 per cent, basophils, 0.5 per cent, lymphocytes, 9.0 per cent, and monocytes, 1.0 per cent. The bone marrow of this animal was slightly congested and the majority of cells were neutrophilic elements. Neutrophils were not as predominant as found in the previous dog which was autopsied while the leucocyte count was 46.0 thousand cells per cu mm. Differential counts (table 2, No. 9) revealed that 86.4 per cent of marrow cells were neutrophilic ele-

ments while only 7.6 per cent of cells were erythroid in nature. These figures should be compared with 43.7 per cent neutrophilic and 40.4 per cent erythroid elements found in the normal dog.

Dog No. 11 This animal was injected for twenty-five days with a total of 89.0 mg of stilbestrol. The leucocyte count increased from 11.6 thousand cells per cu mm to 34.5 thousand cells, and then decreased to 18.8 thousand cells at the time it was sacrificed. At autopsy the erythrocyte count was 5.88 million cells per cu mm, hemoglobin, 14.0 Gm, neutrophils, 67.0 per cent, eosinophils, 2.0 per cent, basophils, 0.5 per cent, lymphocytes, 30.0 per cent, and monocytes, 0.5 per cent. The majority of the neutrophils were of the older variety—a shift to the right.

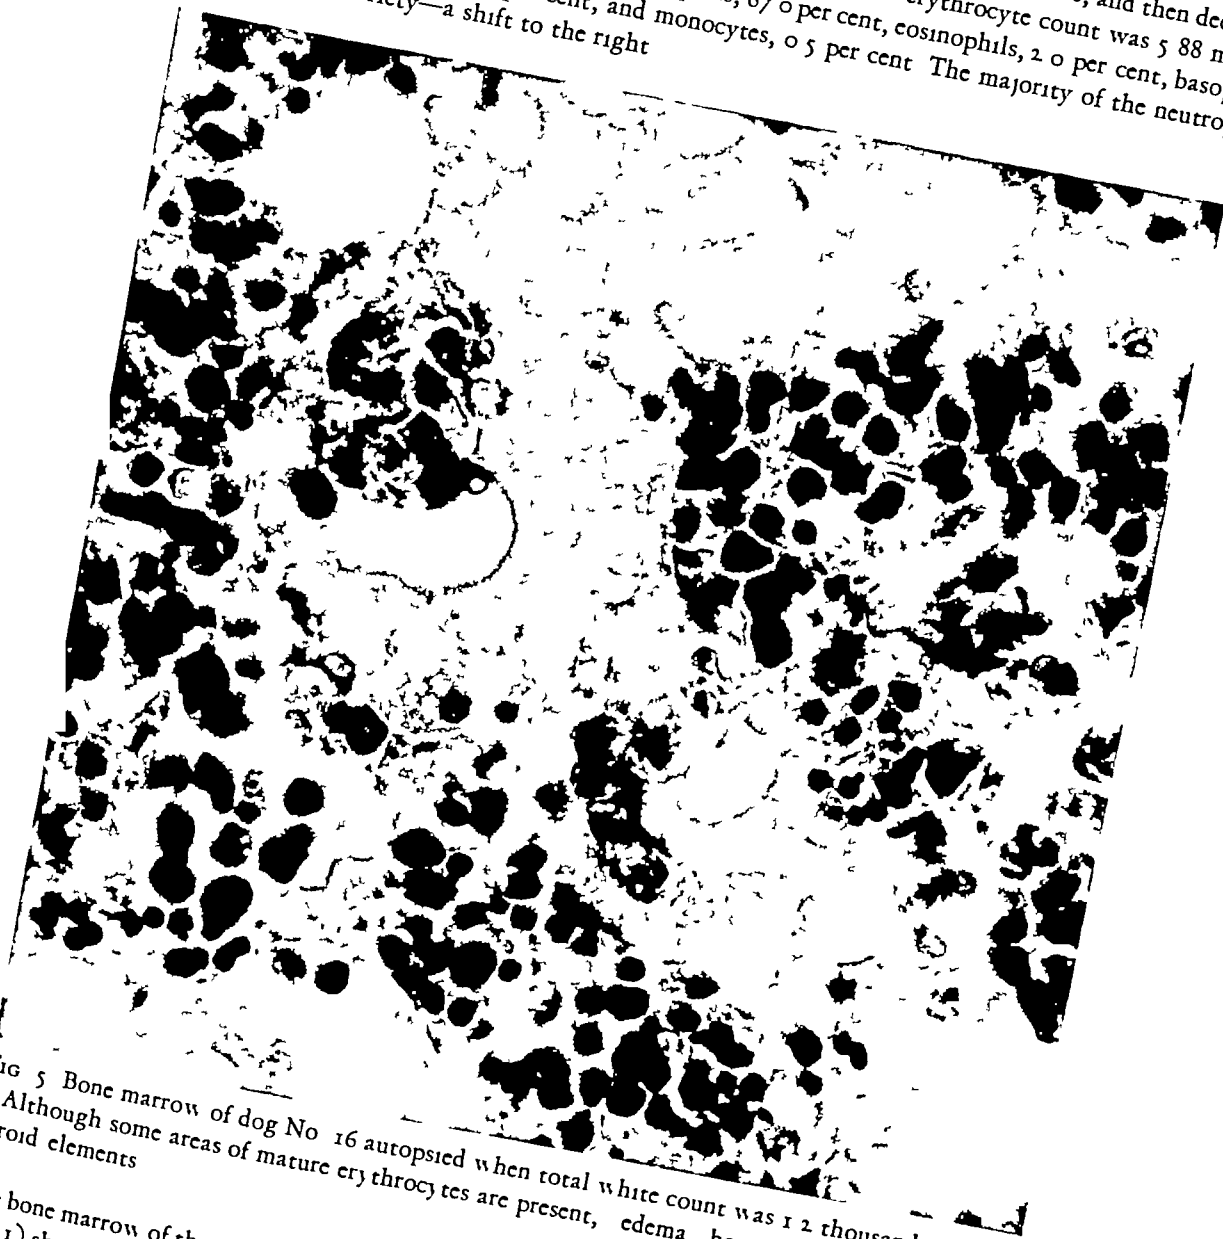

FIG. 5. Bone marrow of dog No. 16 autopsied when total white count was 12 thousand cells per cu mm. Although some areas of mature erythrocytes are present, edema has replaced everything but the erythroid elements.

The bone marrow of this animal looked like marrow from a normal animal. Differential counts (table 2, No. 11) showed, however, that 64.8 per cent of marrow cells were neutrophilic elements and 31.4 per cent erythroid elements.

Dog No. 12 This animal was treated with 5.0 mg of stilbestrol per day for one hundred and twenty-two days. The leucocyte count increased from 19.2 thousand cells per cu mm to 46.9 thousand cells on the eighteenth day of treatment, decreased to 4.0 thousand cells on the forty-third day of treatment, again increased to 26.0 thousand cells on the eighty-first day of treatment, and then gradually decreased to 0.8 thousand cells on the one hundred and twenty-second day, the day the animal was sacrificed. The erythrocyte count decreased from 7.0 million cells per cu mm to 2.6 million cells, hemoglobin, from

15.2 Gm per 100 cc to 7.0 Gm. The blood smear, made on the last day of treatment, did not contain enough cells to make a complete differential blood count. Of the cells counted (60) 11.0 per cent were neutrophils, 2.0 per cent, eosinophils, and 87.0 per cent were lymphocytes.

The bone marrow of this animal was extremely congested. Most of the area in the bone marrow was taken up by mature erythrocytes (figure 4).

Differential counts (table 2, No. 2) revealed a complete lack of neutrophilic elements. 96.5 per cent of the marrow cells were erythroid elements. There was a considerable deposit of hemosiderin pigment in this bone marrow.

FIG. 6 Bone marrow of dog No. 1 autopsied when the total white cell count was 200 cells per cu. mm. Note the almost complete replacement of the remaining erythroid elements with edema.

Dog No. 16 This dog was treated for thirty-three days with a total dose of 93.5 mg. of stilbestrol. The leucocyte count increased from 9.5 thousand cells per cu. mm. to 22.7 thousand cells on the twentieth day of treatment. The animal was sacrificed on the thirty-third day when the leucocyte count was 12 thousand cells per cu. mm. This animal did not exhibit an anemia. The erythrocyte count was 5.37 million cells per cu. mm. and the hemoglobin was 13.5 Gm. per 100 cc. There were not enough white cells on the blood smears to make a differential count.

The bone marrow of this animal (figure 5) showed the same lack of neutrophilic elements as shown in the previous animal, but the areas of extreme congestion were supplanted by a moderate congestion plus large areas of edema. Erythroid elements stood out more clearly. Active erythropoiesis was present and the bone marrow had considerable hemosiderin deposit.

Differential counts (table 2, No. 16) showed results similar to those found in the previous animal: 97.4 per cent of the marrow cells were erythroid elements while only 0.6 per cent were neutrophilic elements.

Dog No. 1. This dog received 50 mg. of stilbestrol per day for thirty-four days. The leucocyte count increased from 13.8 thousand cells per cu. mm. to 54.0 thousand cells on the twenty-third day of treatment. The animal was sacrificed when the leucocyte count was 0.2 thousand cells per cu. mm. The erythrocyte count decreased from 6.18 million cells per cu. mm. to 4.40 million. There were not enough cells in the blood smear to make a differential count.

The bone marrow of this animal (figure 6) was almost entirely devoid of cells. The whole marrow was replaced by the "edema" present. There were not enough cells to make a differential count.

In summary, large doses of estrogen are toxic to the bone marrow of adult dogs. Under the influence of estrogen treatment there is a great stimulus to the production of neutrophilic elements (figure 3), with a concomitant increase in the white cells of the peripheral blood. This accounts for the increase in leucocyte count which invariably follows treatment of dogs with large doses of estrogen. At this stage the majority of neutrophils are of the young variety—a shift to the left. Continued estrogen treatment results in a marked congestion of the bone marrow (figure 4), which is accompanied by destruction of white cell elements. This accounts for the marked decrease in the leucocyte count in the blood stream. The neutrophils in the blood are old—a shift to the right. The areas of the bone marrow formerly occupied by mature erythrocytes and the white cell elements are then replaced by "edema" which, for a time, spares erythroid elements (figure 5). Continued treatment is toxic to the remaining erythroid elements so that the marrow becomes almost completely devoid of cellular elements (figure 6).

DISCUSSION

Estrogens, in large doses, appear to be very toxic to the bone marrow of dogs. Arnold and co-workers² have reported results essentially similar while Dougherty, Williams, and Gardner¹⁹ reported, in abstract form, that estrogens produced an aplastic bone marrow.

There are indications that the effects of estrogens on dogs are due to their toxicity to this animal rather than to any physiological estrogenic activity. One adult female dog was treated with daily doses of 50 mg. of alpha estradiol and another, of similar size and weight, was treated with 50 mg. of beta estradiol, known to have one fortieth of the estrogenic potency of alpha estradiol. Both animals responded to the injections with a great increase in the total leucocyte count followed by a marked decrease.¹¹ The neutrophils were responsible for these changes. In addition, 2 dogs were treated with daily doses of 0.15 mg. of alpha estradiol,* an amount which would approximately represent the physiological activity of daily doses of 50 mg. of beta estradiol. Except for an initial slight rise in the leucocyte count, these animals showed no ill effects after a year of injections.

It is of interest that injections of 10 mg. of estrogen per day produced no such reaction in monkeys,¹¹ and there are no indications that the human responds in any such manner.

* This alpha estradiol was very generously furnished by Dr. Erwin Schwenk of the Schering Corporation.

Dogs respond to estrogens according to their physical condition. While one animal will live for one hundred twenty-six days receiving a daily dose of 50 mg of estrogen and exhibit several increases and declines of the leucocyte count, other dogs will die in thirty days with the same dose. One dog, not reported, received only 0.5 mg of alpha estradiol per day and died on the seventy-sixth day of treatment with a bone marrow completely devoid of cellular elements. This bone marrow resembled that shown in figure 6. At autopsy, this animal was found to be suffering from a respiratory infection and had many intestinal parasites.

Estrogens are toxic to the bone marrow of adult dogs. The toxic dose level differs from animal to animal depending upon its physical condition.

SUMMARY

Large doses of estrogens have a profound effect on the bone marrow of adult dogs. The initial reaction is a great increase in the number of neutrophilic elements in the bone marrow. These neutrophils are released into the blood stream causing a marked rise in the total white cell count. This is followed by congestion of the bone marrow and a destruction of the white cell elements in these marrows. Congested areas and locations formerly occupied by white cell elements are replaced by edema, leaving erythroid elements intact. This accounts for the marked drop in the total white cell count in the blood stream. This is followed by destruction of remaining erythroid elements in the bone marrow and replacement by "edema" until a stage is reached where practically no cells can be found in the marrow.

THE FREQUENCY OF MEGAKARYOCYTES IN AUTOPSY SECTIONS

By ROBERT BRILL, M D ,* AND M M HALPERN, M D †

THE PRESENCE of megakaryocytes in tissue sections has been frequently reported as a significant finding¹⁻⁷ According to Petri⁸ who reviewed the literature, Muller was the first to note the occurrence of megakaryocytes in organs Aschoff often observed them in the lungs in infectious diseases, and less frequently in the kidneys, liver and myocardium Bunting,³ in a study of bone marrow and lung sections in 11 cases of Hodgkin's disease, found megakaryocyte nuclei in the lung capillaries of all cases, in 4 of these he thought megakaryocytes were more numerous than to be expected in cases with marked leukocytosis There was an increase in the number of marrow megakaryocytes in 3 of the 5 cases studied

In cases of active tuberculosis, Medlar and Sasano⁶ noted numerous megakaryocytes in the lungs Orbison¹ reported a case of lobar pneumonia with widespread distribution of megakaryocytes in the lungs and many other organs Goroncy⁷ found megakaryocytes in the lesser circulation (lungs) in 61 per cent of his series of autopsies, in 13 per cent they were observed also in one or more of the organs supplied by the greater circulation, in only 3 of these necropsies were they found in the lungs, spleen, liver and kidneys of the same case Petri⁸ also lists their presence in the bone marrow capillaries and sinusoids of the lymphoid tissue Downey and Nordland,⁵ in a case of myeloid leukemia, observed megakaryocytes in the cortex of the adrenals and the surrounding fatty tissue, as well as in other organs

Most investigators^{2, 9-15} feel that megakaryocytes appear in the organs in conditions associated with increased hematopoietic activity, a viewpoint first expressed by Aschoff Hewer,¹⁶ in a case of osteosclerotic anemia, observed many megakaryocytes in the spleen Because of their absence in the lung sections, he concluded that in this case they were formed in the spleen Downey, Palmer and Powell⁴ found megakaryocytes in liver and spleen biopsies in a case of atypical myelosis, and thought they were produced in situ Klemperer,¹⁷ in his report of cavernomatous transformation of the portal vein, noted numerous megakaryocytes in the spleen He was undecided as to whether or not they were "carried to the spleen by the blood stream, because even when present in great numbers in the venous sinuses they were not found in the arteries" Howell and Donahue¹⁸ maintained that megakaryocytes developed in the lungs from "myeloblastic cells in the same manner as they do in the liver, spleen and bone marrow" However, Jordon¹² did not agree with this conclusion

There have been several reports of the unusual finding of intact or fragmented megakaryocytes in the smears of peripheral blood^{5, 13, 15, 19} Minot¹⁹ stated that they were present in the peripheral blood smears in cases of myelogenous leukemia, polycythemia, and rarely in "simple leukocytosis," lobar pneumonia, Hodgkin's

† Now with Department of Cardiology, Mt Sinai Hospital, New York City

disease and sepsis. He believed that it was indicative of "intense bone marrow strain." Downey⁵ stated that megakaryocytes appeared after splenectomy in the peripheral blood smears from a case of myelogenous leukemia.

This problem was pursued at the suggestion of Dr. William Antopol and Dr. Lester Goldman, who had observed the frequency of megakaryocytes in paraffin sections and felt that they were partially filtered out in the lungs and that the spleen had a special affinity for actively arresting and fixing them therein. It was decided to study megakaryocyte occurrence in the tissues of 50 autopsy cases.

METHODS AND MATERIAL

The first 27 cases chosen for study were cases such as bacterial endocarditis, pneumonia or metastatic carcinoma, in which megakaryocytes were expected to be found. Then 7 autopsies were selected with no history of infection, neoplasm or blood dyscrasia, in which tissue megakaryocytes were not expected to be found. To round out the number an additional 16 random cases were studied.

The diagnoses in the 50 cases were as follows: 9 cases of neoplasm with metastases including bone, 7 of pneumonia, 7 of rheumatic heart disease, 3 of acute bacterial endocarditis, 3 of subacute bacterial endocarditis, 3 of pulmonary tuberculosis, 3 of cardiovascular-renal disease, 2 of Hodgkin's disease, 2 of leukemia, and one each of periarteritis nodosa, Libman-Sacks disease, chronic glomerulo-nephritis, granulomatous ulcer of the buttock, hypoglycemic shock, methyl alcohol poisoning, syphilis of the central nervous system, Landry's paralysis, traumatic death, primary amyloidosis, and a postoperative death.

Studied, but not included in this group of 50, were an additional 4 cases which showed extramedullary hematopoiesis.

With routine hematoxylin and eosin stain, the appearance of the megakaryocyte in the peripheral capillaries differs somewhat from that in the bone marrow. In the latter site the megakaryocyte is round, it possesses an abundant, homogeneous pink cytoplasm, the edge of which may or may not be irregular, the nucleus is large, vesicular or pyknotic, and may have few or many lobules. In the tissue capillaries, the megakaryocytes assume various shapes, being distorted by the channels in which they lie, their cytoplasm is often not discernible and the nucleus may appear naked (fig. 1). To a great extent, identification of megakaryocytes depends on their intravascular location and their enormous size, and especially on the large multilobulated nucleus which is most often pyknotic. Megakaryocytes with abundant cytoplasm are occasionally present, particularly in the wider channels (fig. 2).

In the lungs, the megakaryocytes are most frequently found in the capillaries of the alveolar septa. The glomerular tufts are their usual site in the kidneys, however, they are also seen in the interstitial capillaries. In the liver and spleen sections they are usually found in the blood sinuses. In heart sections they appear in the capillaries between the muscle fibers.

When megakaryocytes were found in the organs, a rough estimate of their number was recorded as being one to three plus. When only two or three megakaryocytes were found in the examination of a whole paraffin section, about 1 cm

FIG. 1 ALMOST NAKED MEGAKARYOCYTE NUCLEUS IN A GLOMERULAR CAPILLARY

FIG. 2 MEGAKARYOCYTE WITH ABUNDANT CYTOPLASM IN THE PULMONARY CIRCULATION

square, a one plus was recorded. Those cases with large numbers of megakaryocytes, averaging 1 or more per low power field (16 mm objective and 10 \times ocular), were considered three plus. Two plus represented the intermediate group. No attempt

was made to use absolute numbers first, because of the difference in anatomical blood supply in the different organs, secondly, because of the varying pathologic changes in the same organ in different cases

RESULTS

In all of the 50 cases studied, megakaryocytes were demonstrated in the lungs. Their presence in smaller percentages was noted in the spleen, kidney, liver and heart (table 1). Megakaryocytes were noted in the adrenals in two cases, and in the pancreas and stomach in one instance each, but these are not included in the table.

P	P	O	O	P	1

P megakaryocytes present

O megakaryocytes not found

Sections of all the five organs mentioned in table 1 were available for study in only 40 of the 50 cases. The simultaneous occurrence of megakaryocytes in one or more of these five organs of each of these 40 cases is listed in table 2. It will be noted that megakaryocytes were found in the lungs alone in 16 cases, and in the lungs and spleen in 6. There were 12 cases with megakaryocytes present in the lungs, spleen, kidney and liver, and in 5 of these, megakaryocytes were also seen in the heart. Smaller numbers of other combinations are listed in table 2.

There appeared to be some correlation between the concentration of megakaryocytes in the lung capillaries and their occurrence in other organs (fig 3). Seventeen cases demonstrated a one plus megakaryocyte concentration in the lungs; no megakaryocytes were found in the other organs in 11 of these cases, in the other 6 cases, they were found only in the spleen or in the spleen and one other organ.

Eleven cases showed a two plus megakaryocyte concentration in the lungs

Five of these had no megakaryocytes in the other organs. In 4 more, they were demonstrated only in the spleen or the spleen and one more organ. In the 2 cases with involvement of all five organs, the megakaryocytes were numerous in the lungs, but not sufficiently numerous to fall into the three plus category.

All 12 cases with a three plus concentration in the lungs had megakaryocytes also in other organs. In 3 cases all five organs were involved, and in 7 more, megakaryocytes were demonstrable in all but the heart.

FIG 3 CORRELATION BETWEEN THE MEGAKARYOCYTE CONCENTRATION IN THE LUNGS AND THE NUMBER OF OTHER ORGANS INVOLVED

One interesting finding was the constant presence of megakaryocytes in the spleen, whenever there was involvement of organs besides the lungs (table 2).

The diagnoses in the 12 cases (table 2) with involvement of four or five organs were pneumonia, acute or subacute bacterial endocarditis and carcinoma with metastases.

In the 4 cases with extramedullary hematopoiesis, it was possible to show, in one or another of the organs, a megakaryocyte concentration roughly as great as, or greater than that in the lungs.

DISCUSSION

The greatest incidence of extramedullary megakaryocytes appears to be in the lungs. This fact suggests, in agreement with earlier investigators, that their

presence is dependent upon their delivery into the peripheral blood from the bone marrow and their subsequent filtration by the pulmonary capillary bed

From the data presented one might conclude that with more megakaryocytes entering the blood stream from the marrow, more will reach the lungs, and in turn, the more that filter through the pulmonary capillary bed, the more will be carried to other organs

One might also conclude that under normal conditions variable numbers of megakaryocytes enter the blood stream from the bone marrow and can be demonstrated in the lung capillaries. The number of these is frequently increased in disease processes. Those megakaryocytes passing the pulmonary capillary bed are most frequently demonstrated in the spleen

SUMMARY

- 1 Megakaryocytes can be demonstrated with great frequency in the viscera
- 2 Megakaryocytes were present in the lungs in all of 50 autopsies studied
- 3 They were next most frequently found in the spleen
- 4 The simultaneous occurrence in the various organs, in the absence of extramedullary hematopoiesis, is roughly related to the concentration in the lungs
- 5 Under normal conditions megakaryocytes in small numbers circulate in the blood stream

FEMORAL BONE MARROW BIOPSY IN THE ALBINO RAT

By D G CAMERON, B Sc , M D , AND G M WATSON, M B

IN THE course of another investigation we became interested in studying the myelogram of the rat with a view to observing changes which might occur as the result of experimentally induced anemias. The scanty published work on this subject has been recently referred to by Vogel (1947). She has also developed a method for obtaining marrow and has given a detailed description and classification of the cell types. The limitation of her method is that the animal must in each instance be sacrificed. The present investigation was therefore directed towards the development of a reliable method by which repeated marrow studies of one animal could be made.

METHOD

Marrow films were made from twelve healthy albino rats of the Wistar strain, aged 4 to 6 months. The rats were fed on a diet which we have found to maintain them in good condition, and to permit normal growth and reproduction (table 1).

To obtain marrow samples, the skin over the femur is depilated by clipping short and then swabbing with 40 per cent sodium sulphide. The animal is anesthetized with ether and tied on its side. Aseptic technic is used and a 2 cm incision made along the axis of the femur. The muscles are then separated to expose the widened upper end of the femur, which can be grasped with a pair of toothed dissecting forceps. Using a sharp 20-gage needle as an awl, a hole is drilled into the marrow cavity. A cannula, previously prepared by filing the bevel and point from a 20-gage needle, and mounting it on a 2 ml all glass syringe, is then introduced into the marrow. Before introduction, human plasma is aspirated into the syringe and then expelled, so that plasma remains in the cannula but not in the syringe. Suction is applied until marrow just shows in the syringe and the cannula is then withdrawn. The marrow, already mixed with plasma, is expelled onto a series of slides, and films are made and quickly air-dried in the usual manner. From six to eight films can be made without difficulty. The muscles are brought together with a single cotton suture. The skin is closed, with either a continuous eversion cotton suture or Michel clips. The wound is sealed with collodion. No other dressing is applied. Clips are removed in forty-eight hours but sutures may be left. The animals have no disability after the operation and the wound is healed within a week.

RESULTS

A second biopsy can be made from the same femur after a fortnight. Marrow films from the second femur can be made as soon as two days after biopsy of the first femur. The range of cellular distribution is not altered in these instances. By using the femurs alternately, satisfactory examinations of the marrow can be made at weekly intervals.

* Human plasma was used in preference to rat plasma because it was readily available and gives satisfactory results (Endicott, 1945)

marrow with plasma in the cannula than by using undiluted marrow, or by diluting the marrow on the slide in a drop of saline or plasma

Differential counts were made from films prepared by this method, 1000 cells being counted in each instance. May-Grunwald-Giemsa staining was used throughout. Although there was considerable variation in distribution, the morphology did not vary in the series. The counts are summarized in table 2, employing a modification of the classification used in this department for reporting on sternal marrow smears. This classification differs in a few respects from those used by other authors.

Primitive cells, which cannot be differentiated with certainty, we have labelled "blast" cells, the majority are presumably myeloblasts.

Neutrophilic granulocytes of greater maturity than myelocytes have been classified as young forms, staff cells and mature neutrophils. We agree with Vogel (1947) that the ring cell is more mature than the myelocyte, but we find that the nucleus of the granulocyte, at all stages of maturity beyond the myelocyte, may have a ring formation. It is therefore necessary to consider all the characteristics of a ring cell before assessing its maturity. Most of the ring cells are here classified as young forms, together with Vogel's metamyelocytes.

Eosinophilic granulocytes have been classified into two groups only: myelocytes and mature forms. Ring forms are also present in the eosinophil series.

No precursors of basophilic granulocytes were observed.

Cells of the erythropoietic series have been divided into four groups with descriptive names. The differentiation of the proerythroblast from other "blast" cells is difficult and cannot be accomplished with certainty by the present methods.

There was no sex difference in the myelograms.

SUMMARY

A technic for repeated femoral bone marrow biopsy in the rat is detailed.

Differential counts confirmed the distribution of the cellular elements as described by other authors.

THE OCCURRENCE AND SIGNIFICANCE OF "MOTILE" ERYTHROCYTES IN HUMAN BLOOD AND MARROW IN ANEMIC STATES*

By PAUL H. RALPH, M.D.†

IT HAS frequently been observed that fixed films of blood from macrocytic anemias, e.g., pernicious anemia, are characterized by poikilocytosis to a degree not seen in other anemic states. The study of living blood presents new facts of interest to the cytopathologist which contribute to the explanation of this phenomenon.

The dark-field microscope is particularly suited to the study of living blood cells since the smallest organoids are visible without stains or other alterative treatment and the most delicate of membranes appear as lines of varying thickness and refractivity.⁶ Consequently, all descriptions in this paper, unless otherwise specified, are of the dark-field appearance of the structures concerned. Because of better reproducibility, the photographs are given as negative rather than positive prints. Artifact formation was kept at a minimum by using only freshly drawn material and by handling it with the greatest care.

In a number of anemias of varying etiology (Hodgkin's disease, leukosarcoma, pernicious anemia et al.) it was noted that some erythrocytes of the peripheral blood exhibited irregular cell surfaces. The membrane of these cells (figs 1-5, plate I) was less thick and refractive than that of the red blood cells of typical discoid shape. This appearance of the cell surface denotes a lower concentration of hemoglobin and a more primitive condition of the cytoplasm.⁶ Although most of these cells contained mitochondria and neutral red-staining granules‡ not all of the cells containing such organelles exhibited motility. Few if any erythrocytes from normal blood contain such structures.⁶

It was noted that this irregular form of the cytoplasm was constantly changing. In the least primitive of these cells the alterations took the form of small shallow notches that repeatedly appeared in their surface at from one to four places and slowly disappeared. In the more primitive forms (figs 1-5, plate I) these constrictions were much deeper and divided the cell into lobes or pseudopods which were slowly protruded and retracted. Coincident with these surface changes the organoids of the cell, sometimes tangled into a knot, slowly moved about as though carried by currents within the cytoplasm. Occasionally in the most primitive erythrocytes a tiny granule-free area was present, surrounded by a group of neutral red-staining granules about which the mitochondria were loosely aggregated—the centrosphere. The sum of all these activities constitutes something that simulates

FIG 6 Megaloblast from bone marrow of patient with Hodgkin's syndrome showing the formation of a large pseudopod with a partial constriction of the cell membrane at its base 1500 X

FIG 7 Same cell as in fig 6, three minutes later Note completion of cytoplasmic constriction

FIG 8 Same cell as in fig 6, six minutes later Note apparent effort of the pseudopod to detach itself from the parent cell

FIG 9 Same cell as in fig 6, thirty-six minutes later Bud is attached to parent cell by thin, slightly refractive thread

FIG 10 Same cell as in fig 6, eighty-seven minutes later Bud has become detached and continues to exhibit motility

amoeboid movement. It differs from amoeboid movement in that the bud does not move from place to place and that the motility is not related to any vital function such as food getting, phagocytosis of debris, etc.

In order to study the origin of such cells, sternal marrow aspirations were obtained from selected patients whose peripheral blood contained large numbers of 'motile' erythrocytes. All such specimens of marrow contained megaloblasts* with reduced amounts of hemoglobin in their cytoplasm, displayed the same cell membrane refractivity and types of mitochondria and neutral red-stainable granules that distinguished the motile erythrocyte in the peripheral blood. Some were polynucleate (fig. 14) and contained more than one central apparatus. In some cases multipolar mitoses could be seen, with as many as seven centrospheres clearly marked out by the clustering of neutral red-stainable granules. These cells gave a positive reaction to the benzidine test for hemoglobin.⁵ After a short time for adjustment to *in vitro* environment, these cells begin to extrude slowly and to retract one or more large blunt pseudopodia. Gradually the base of such pseudopods might narrow (fig. 6, plate I) and when constriction became sufficiently acute, an actual cleavage of the cytoplasm occurred (fig. 7, 8, plate I, fig. 13, plate II). This cleavage at first involved only the hemoglobin-laden endoplasm of the cell. The thin, weakly refractive ectoplasmic membrane at the surface⁶ might remain intact for some time and be visible as a thin gray thread holding the budded erythroplastid to its parent cell (fig. 9, plate I). This strand eventually broke and the newly formed red cell left the mother cell by amoeboid-like movement (fig. 10, plate I). These buds might occur at any place on the cell surface, but there was a tendency for them to be formed near the centrosphere, in which case frequently not only mitochondria but some of the neutral red-stainable granules (fig. 13, plate II), and a part or all of the centrosphere were contained in the bud.

The movement of the newly formed erythroplastid differs from that of the more mature units in the circulation, in that it appears to be more active and the cell moves about from place to place. The motility gradually diminishes in *in vitro* preparations, but it has been seen to persist in individual plastids for as long as five hours after separation from the parent cell.

The formation of buds from leukocytes and connective tissue cells, described as clasmatocytolysis by Ranvier⁷ and as pictured by Cunningham, Sabin, Doan¹, may be of several types and due to a variety of causes. Although a detailed description of these changes is the subject of a further communication, they are here briefly characterized for the sake of comparison.

When exposed to *in vitro* conditions for considerable lengths of time, dark-field illumination demonstrates that the cytoplasmic membrane of living cells becomes much more refractive, thicker and less labile. Eventually the cell becomes permeable to its milieu and imbibes fluid. The cytoplasm becomes markedly less viscous, as evidenced by the acceleration of Brownian movement of organoids within it, and many tiny new granules may be precipitated in the otherwise homogenous

* The term megaloblast is here intended to include the megaloblast as described by Jones,³ et al. and the morphologically similar giant erythroid elements found in a variety of dyscrasias. They both exhibit the motility and budding described in this paper.

PLATE II

FIG 11 Same cell as in fig 6, one hundred and seventy minutes later Motility continues

FIG 14 Tri-nucleate megaloblast from patient with Hodgkin's disease forming three erythrocytes by budding 1180 X

cytoplasm Amoeboid movement may persist in cells in which these changes have taken place, although it is sluggish and altered qualitatively Portions of the cell

membrane frequently round up and form vesicles which bud from the parent cell. They contain fluid of very low viscosity, organoids and precipita, and are not capable of amoeboid movement. Clasmatoocytes are characterized by the irreversible extrusion of long tubular, worm-like pseudopodia which may or may not separate from the parent cell. This lytic type of budding is due to alterations in permeability of the cell membrane, and is a part of the death process. The budding of the megakaryoblast differs from that just described, in that it takes place in the living body, the bud is motile, carries out its normal function, i.e., transport of oxygen, and the parent cell does not exhibit moribund changes.

Primitive cells from connective tissue, lymph nodules, spleen and marrow, leukemic and sarcomatous cells and normal, but immature cells mobilized into the peripheral blood by unusual stimuli, are frequently delicate and at the same time turgid and incapable of amoeboid movement. They often fragment without exhibiting many of the lytic changes previously described. The bud produced contains the organoids of the parent cell and exhibits the characteristics of the intact parent cytoplasm. It differs from the budding described for the red cell in that the bud is not motile, serves no useful function and is produced by the mechanical action of an unsuitable environment upon the cell.

The budding of platelets from megakaryocytes, although poorly understood is differentiable from the budding of megalo- and normoblasts because of qualities of the thromboplastid itself. The platelet is an extremely labile thixotropic system which changes irreversibly from a rigid gel to a sol on contact with any wettable surface. Eventually vesicles bud from its surface similar to those formed by the action of *in vitro* conditions upon normal cells.

The question then arises, are these "motile" erythrocytes to be construed as specific entities pathognomonic of the disease in which they are found or are they merely evidence of a greater or lesser "left shift" of erythroid elements in the marrow with a larger percentage of the circulating cytoplasmic units derived from more primitive cells. The mouse (Klieneberger²) and the rabbit (Seyfarth⁹) normally have many more circulating reticulocytes than does the adult human. In a study of normal adult rabbits the author found some quite motile erythrocytes in every sample of blood examined. They contained mitochondria and neutral red-staining granules and were in every way similar to those found in human macrocytic anemia except that there was not the great variation in size and shape nor the pronounced hypochromia. The same phenomenon was found in the mouse except that fewer of the cells showed motility. Young animals of both species showed more motile erythrocytes than did the adults.

DISCUSSION

The *normal* process by which a mammalian erythrocyte is produced is one of budding in which the parent cell, i.e., the normoblast, becomes separated into two fragments. One contains a pyknotic nucleus, a shred of cytoplasm, and perhaps a few cellular organoids, the other is a disc of hemoglobin-laden cytoplasm with a cell membrane and occasionally a few mitochondria and neutral red-staining granules. This process has been seen to occur *in vitro* by the author. It is, therefore,

perhaps inaccurate to speak of the normoblast as "extruding" its nucleus merely because the division is usually unequal and the nucleus-containing fragment smaller and sometimes apparently devoid of cytoplasm. In the normal human adult the reticulocyte exhibits no motility. This is because the normoblast from which it buds is so mature as to have lost this quality. Under conditions in which the marrow is unable to supply erythrocytes from mature normoblasts, younger and younger cells, with less hemoglobin and with other evidences of immaturity such as the presence of mitochondria and neutral red-staining granules, a more fluid cytoplasm, and amoeboid movement are called upon to supply these small packages of respiratory pigment, the erythrocytes. Naturally, these red cells will to a certain extent exhibit the characteristics of their parent, i.e., hypochromia, motility, content of organoids, etc.

Werner Schultz⁶ in a report based on a single case of untreated pernicious anemia described the formation of erythrocytes (blastopodocytes) by localized budding of the cytoplasm of megaloblasts. He regarded this budding as the true origin of the poikilocyte, and as a "pathological regeneration" limited to the megaloblast of pernicious anemia in the human adult and, consequently, a point of "functional" differentiation between this cell type and the "macroblast" of some other anemic states. We cannot support his conclusions. First, we have found this budding to occur in a variety of conditions other than pernicious anemia. Second, poikilocytosis and "motile" erythrocytes are by no means limited to pernicious anemia but may occur in the human adult in a variety of anemic states and in the rabbit and mouse under normal conditions. The presence of large numbers of poikilocytic and motile erythrocytes is due to the absence of normal blast forms from which they may be budded.

SUMMARY

1 With the aid of supravital studies and dark-field illumination, "motile" erythrocytes (capable of self initiated amoeboid-like change in form and, in some cases, movement from place to place) may be found in the peripheral blood of cases of anemia, particularly those of the macrocytic variety.

2 These motile erythrocytes are usually hypochromic, contain mitochondria and neutral red-stainable granules, all of which are attributes of normal but immature red cells.

3 Motile erythrocytes similar to those found in the blood of human patients with anemias are found in the blood of normal rabbits and mice.

4 In the marrow of patients with macrocytic anemias, megaloblasts and megalo-cytes may be found which give rise to motile erythrocytes by budding.

5 Poikilocytosis, motility, paleness, content of mitochondria and neutral red stainable granules, and origin by budding from a large parent cell do not differentiate the erythrocytes of pernicious anemia from those of other anemic states.

CASE REPORT

ULCERS OF THE LEG IN MEDITERRANEAN DISEASE

B₃ J EARLE ESTES, M D , EUGENE M FARBER, M D , AND J M STICKNEY, M D

MEDITERRANEAN disease, better known as Cooley's anemia, has been recognized as a distinct clinical entity for only a little more than two decades. In spite of this fact, an extensive literature on this comparatively rare disease has been developed and has recently been reviewed by Wolman and Dickstein.¹ It was not recognized until recent years that Mediterranean disease occurred in adult persons as well as in children. What was formerly considered to be a severe, invariably fatal disease of childhood has been found to be a disease which varies greatly in severity. It may be so mild as to give rise to no clinical symptoms. A carrier state has been thought to exist in which, although a person does not have symptoms of Mediterranean disease, he may pass on to his progeny a genetic trait which ultimately may result in a clinically recognizable form of the illness. Thus, Mediterranean disease can exist in a patient of any age, and it may be severe, mild or clinically detectable only by a thorough study of the blood.

Three adult patients who had Mediterranean disease of varying severity were studied at the Mayo Clinic in October of 1946. They were sisters of Italian descent, all 3 at one time or another had had ulcerations of the skin of the legs. A study of the literature on Mediterranean disease has failed to disclose mention of ulcers of the leg occurring in this type of anemia. It is the purpose of this paper to report ulceration of the skin of the legs as a manifestation of Mediterranean disease. Each of these patients stated that she had been anemic many years, and that a diagnosis of Cooley's anemia had been made many times.

The first patient was a 30 year old Italian woman who complained of soreness in the right upper abdominal quadrant. She had been informed by her local physician that she had gallstones. When she had been 14 years old, ulceration of the skin over the medial aspect of the left ankle had developed. This had lasted about a year and had healed slowly, leaving a scar. During the general physical examination moderate pallor of the oral mucous membrane was seen. There was tenderness to deep palpation in the right subcostal region, and the tip of the spleen could be felt 4 cm. below the left costal margin. A small pigmented scar was seen over the medial aspect of the left ankle. There were no other significant physical observations. Except for the ulcers on the leg, this patient had not been incapacitated by her disease.

The second patient was 23 years old. She came to the clinic because of an ulcer of the skin on her right leg. When she had been 12 years of age, two ulcers over the midportion of the right leg had developed. These had lasted for two years and finally had healed, leaving scars. At 15 years of age an ulcer above the right lateral

From the Division of Medicine and Section on Dermatology and Syphilology, Mayo Clinic and Mayo Foundation, Rochester, Minnesota.

malleolus had appeared and had lasted for two years before it healed. At 20 years an ulcer had developed above the left lateral malleolus. This had been treated with balsam of Peru, but at the time of the examination it had not healed. In spite of long-existing anemia, in which the patient said the value for hemoglobin had averaged 8 Gm per 100 cc of blood for many years, she had not been incapacitated except by the ulcers of the leg. During the general physical examination a yellow pallor of the skin was noted. A systolic murmur was heard over the entire precordium. The spleen was palpable 7 cm below the left costal margin, and the liver

FIG. 1. INDOLENT ULCER ON THE LEFT LEG OF A FEMALE PATIENT TWENTY-THREE YEARS OLD WHO HAD MEDITERRANEAN ANEMIA. NOTE THE ATROPHIC SCARS AT THE SITES OF OLD HEALED ULCERS.

was enlarged to a point 3 cm below the right costal margin. An ischemic-appearing indolent ulcer 4 cm in diameter was present on the lateral surface of the left leg above the external malleolus (fig. 1). The border of this ulcer was irregular, but was not undermined. There was considerable hyperpigmentation at the periphery of the ulcer, but in this zone there was only minimal cutaneous sclerosis. The base of the ulcer was clean. Three scars, the sites of previous ulceration, were noted (1) on the right leg, (2) on the anterior surface of the left leg, in its upper third part and (3) on the lateral surface of the left leg. These scars had a hyperpigmented periphery and a glossy, atrophic center. There were no other significant physical observations.

The third patient was 19 years old. She came to the clinic because she had an ulcer on her right ankle which had remained unhealed for a year. When she had been 17 years old an ulcer on the left ankle had developed which had been treated with penicillin without apparent effect. This ulcer had healed slowly over a period of eighteen months. A year later an ulcer on the right ankle had appeared and had been treated with balsam of Peru, but it had not healed.

During the general physical examination pallor of the mucous membranes and yellow pallor of the skin were noted. The heart was enlarged and the apical impulse could be palpated at the anterior axillary line. A loud blowing systolic murmur was heard over the entire precordium, and it was maximal at the cardiac apex. Dyspnea was evident when the patient was at rest, and was pronounced after any exertion. The spleen extended to the umbilicus, and the liver was palpable 7 cm below the right costal margin. A triangular ulceration of the skin 1.5 cm in diameter was noted just distal to the right external malleolus. This ulcer was similar to the one described in the second patient. The present patient was suffering from a severe form of Mediterranean disease, and was greatly handicapped.

In none of these patients was there evidence of arterial or venous insufficiency in the extremities. Local treatment for the ulcers and the administration of iron, liver extract and whole blood had not brought about any improvement in the ulcers or the general health of the patients. In roentgenograms of the skull, only those of the third patient demonstrated changes of significance. General osteoporosis, with thinning of both the inner and outer tables of the skull, was noted.

In smears of specimens of blood from all 3 patients similar changes characteristic of Mediterranean disease were seen. The changes were of a severity in proportion to the extent of the anemia. These changes consisted of a great variation in the size and shape of erythrocytes, with many microcytes but no spherocytes. Hypochromasia and polychromatophilia were marked, and normoblasts were present. Target cells were seen in all smears, but they were not conspicuous. Myeloid immaturity was not noted.

Studies of sternal bone marrow were made in each case. In all three there was hyperplastic erythropoiesis of the normoblastic type. Megaloblasts were not seen. It may be of some significance that the mature erythrocytes in the marrow smears were of more uniform size and shape than were those seen in specimens of peripheral blood. Pertinent laboratory data are summarized in table 1.

The diagnosis of Mediterranean disease was made in these three cases on the basis of familial anemia, increased resistance of the erythrocytes to hemolysis in hypotonic solution of sodium chloride, very active normoblastic erythropoiesis, and the failure of the anemia to respond to any therapy. No other cause for the anemia could be found. Sick cell anemia was eliminated by the absence of sickling, and congenital hemolytic icterus, had it been present, should have produced spherocytosis and increased fragility of the erythrocytes.

A piece of skin was removed for biopsy from the margin of the ulcer on the leg of the 23 year old patient. Epidermal changes consisted of minimal hyperkeratosis and irregular acanthosis. In the upper half of the cutis the capillaries and arterioles

were increased in size and number, and there was moderate infiltration of lymphocytes, connective-tissue cells, chromatophores and polymorphonuclear leukocytes. In the midportion of the cutis there were several areas of beginning necrosis with

FIG 2. SPECIMEN TAKEN FOR BIOPSY FROM THE MARGIN OF AN ULCER ON THE LEG OF A PATIENT WITH MEDITERRANEAN ANEMIA, SHOWING DENSE DEPOSITS OF IRON IN THE MIDPORTION AND LOWER PORTION OF THE CUTIS (HEMATOXYLIN AND EOSIN $\times 25$)

disintegration of cells, so that recognition of cell types in these areas was not possible. Elastic tissue was absent throughout the upper portion of the cutis, and very little elastic tissue was present in the vessels. Degenerative changes, homo-

genization of collagen and moderate edema were seen in the arteriolar walls. In occasional vessels there was proliferative intimal thickening, although in most of the vessels there was no significant alteration of wall-to-lumen ratio. Dense deposits of iron (fig. 2) were seen in the midportions and lower portions of the cutis stained with ferric thiocyanide.

The dense deposits of iron in these sections are of great interest. Whipple and Bradford² have studied the deposition of iron-containing pigment in the organs of patients who died of Mediterranean disease. They considered this pigment to be as characteristic of the disease as is any other finding. It resembles that seen in hemochromatosis in adult persons and is seen in most of the organs of the body. Whipple and Bradford made no mention of such deposits in the skin. Mills³ has reported results of a postmortem study of the skin of a child who died of Mediterranean disease. He considered the pigment he found to be melanin, and not hemosiderin.

When the differential diagnosis of ulcers on the legs of these patients was considered, it was apparent that the lesions were not secondary to occlusive arterial diseases such as thrombo-angiitis or arteriosclerosis obliterans. The absence of hypertension excluded the possibility of the ischemic type of ulceration occasionally associated with hypertension. Venous stasis could not have caused the ulcers because there were no varicose veins and chronic venous insufficiency was not present. Trophic disturbances such as might be caused by syringomyelia, tumor of the spinal cord or tabes dorsalis were excluded. Chronic granulomas as seen in syphilis, tuberculosis, sarcoidosis or dermatomycosis would have produced different histopathologic changes.

The ulcerations of the skin of the legs which occur in sickle cell anemia and congenital hemolytic icterus do not have a distinctive gross appearance which could be used to distinguish them from each other or from those in the patients we are discussing. It seems to us that the chronic ulcer on the leg of an anemic patient is not pathognomonic of a specific type of anemia. The exact character of the anemia must be determined by appropriate clinical and hematologic study.

SUMMARY

Ulceration of the skin of the legs may occur in Mediterranean disease. Such ulceration cannot be distinguished grossly from that occurring in sickle cell anemia and congenital hemolytic icterus. The outstanding histologic feature (noted at biopsy of one of these ulcers) is the prominent deposition of iron in the cutis.

EDITORIAL

THE HEMOLYTIC CRISIS

THE HEMOLYTIC crisis which occurs so suddenly in cases of familial hemolytic jaundice (familial spherocytosis) has excited interest but its pathogenesis has remained a mystery since it was first described as "crise de déglobulization". Adding to its mystery is its fairly frequent occurrence in successive members of the same family, the cases usually appearing within a few days of each other¹⁻³

During the crisis there is a precipitous reduction in the red cell count, accompanied by such constitutional symptoms as fever, vomiting and malaise. Some blood findings have received relatively scant attention, although occasional observers have noted the rather paradoxical reductions in leukocytes, platelets and reticulocytes which may be present—paradoxical because in excessive blood destruction one expects regenerative efforts on the part of the bone marrow with resultant increases in reticulocytes, leukocytes and platelets. What is more, reticulocytosis is considered almost as pathognomonic a finding of the disease as spherocytosis.

Some years ago, I remarked on the pancytopenia which occurred in three cases of familial crisis¹ and stated that "one may speculate as to whether this is due to a hormonal influence of the spleen on the marrow, with the result that the maturation or delivery of cells to the circulation becomes inhibited." In studying a recent case* Bloom and I found, during the crisis, marked pancytopenia with a complete lack of reticulocytes for four days. Simultaneously, the marrow showed maturation arrest of the nucleated red cells at the primitive or erythrogonic level. When the arrested maturation was spontaneously re-established, reticulocytosis took place in the peripheral blood and the blood counts then returned to pre-crisis levels. We have interpreted the events occurring in crisis as due largely to "hypersplenic" effects with resultant hyperhemolysis, as well as inhibitory effects upon the marrow, the latter resulting in maturation arrest and diminished delivery of marrow cells to the blood.

Owren, whose comprehensive article on the hemolytic crisis appears in this issue, submits a different interpretation for the same set of data. He states that there is no evidence for increased hemolysis during crisis but that the extreme reductions in red cells, leukocytes, platelets and reticulocytes are due to a sudden hypoplastic or aplastic disturbance in the marrow. On the other hand, the extreme spherocytosis of the crisis, the drop in red cell count of from 10 to 30 millions within a day or two of onset and the remarkably quick response in all the various blood cellular constituents which occurs with splenectomy, would seem to argue against Owren's thesis. Nevertheless, Owen's observations are of unusual interest and should serve to provoke further work on the pathogenesis of the crisis, and, indeed, on the fundamental mechanisms of familial hemolytic spherocytosis as well. It is likely that

* Dameshek, William and Bloom, Marvin S. The Events in the Hemolytic Crisis with Particular Reference to Reticulocytopenia. To be published in one of the forthcoming issues of *Blood* dedicated to Dr. George R. Minot.

two mechanisms, acting simultaneously, are responsible for the extremely rapid drops in red cell count (1) maturation arrest and (2) hyperhemolysis

The development of extreme spherocytosis in the crisis might indicate that this was due to the activity of some extrinsic hemolytic factor acting upon mature red cells, thus causing their rapid destruction. If this is true for the crisis, in which we have occasionally found the presence of a serum auto-hemolysin, it is also a possibility for the less marked spherocytosis and anemia during the long periods between crises. In other words, is congenital spherocytosis really due to a fundamental defect in erythropoiesis as most observers maintain, or is it dependent upon the action of some hemolytic factor which may be specific for the individual's own red cells? In favor of this concept is the relatively large size of the polychromatophilic reticulocytes, which are quite in contrast with the more mature orthochromatic spherocytes. This might indicate that 'hemolysin' has converted normal non-nucleated reticulocytes to injured red cells, i.e. the spherocytes. This would take the disease out of the bone marrow and into some vascular or intravascular site. Be that as it may, there are still many unsolved problems in this, the first described and best known form of hemolytic anemia, and a portent of work to come.

ERYTHROCYTES AND ERYTHROCYTIC DISEASE

CHEMICAL FACTORS IN PERNICIOUS ANEMIA *H. K. King* From the Bacteriology Department, Edinburgh University, Edinburgh, Scotland *Edinburgh M. J.* 54 50-60, January 1947

This article summarizes the many attempts which have been made to assay the antianemic factor in pernicious anemia. The limitations of present knowledge of the intrinsic, extrinsic and liver factors are evident from this discussion. With the impetus provided by folic acid towards the isolation of these factors in their pure chemical state, the article is timely in expressing the need for a satisfactory method other than therapeutic trial in patients for assaying newly prepared compounds. One hundred and one references are cited.

C. A. F.

CASTLE'S TEST IN PERNICIOUS TAPEWORM ANEMIA. *DIPHYLLOBOTRIUM LATUM* AND PERNICIOUS ANEMIA VII. *B. von Bonsdorff* Helsingfors, Finland *Acta Med. Scand. Suppl.* 196, Hilding Berglund Anniversary Volume P 456-477, 1947

Tapeworm anemia of pernicious type is the classic problem of Finnish hematology. The author has published a series of very interesting investigations on the gastric secretion in this condition. It has been shown that liver extracts, either intramuscularly or perorally as well as desiccated stomach perorally, are able to induce a remission in this malady. The paper deals with the action of intrinsic plus extrinsic factor in tapeworm anemia. Bonsdorff has already shown that intrinsic factor is present in the gastric juice of these patients. There is no remission if the worm is expelled and the patient is living on a diet free from extrinsic factor (Extrinsic factor however was obviously available in the diets of these anemic patients).

A large series of very thorough experiments were performed and it was found that mixture of extrinsic factor (meat or yeast extracts) and intrinsic factor (human gastric juice) gave no response in tapeworm anemia. The same preparations were active in cryptogenetic pernicious anemia. The results were constantly negative regardless of whether the mixture was incubated for 6 hours before administration or not. The explanation of these data is discussed. It is pointed out that the liver principle itself is not formed *in vitro*. The hypothesis of Formijne that the interaction of the two factors (ex- and in-) takes place in the intestinal wall is discussed. The inhibiting effect of the tapeworm should then occur at this level.

J. W.

THE INTRINSIC FACTOR ACTIVITY OF HIGHLY PURIFIED PREPARATIONS OF AMINOPOLYPEPTIDASE II. *G. Ågren and J. Waldenström* From the Department of Medical Chemistry and the Medical Clinic of the University, Uppsala, Sweden *Acta Med. Scand. Suppl.* 196 Hilding Berglund, Anniversary Volume, p 432-455, 1947

Ågren has pointed out that the intrinsic factor may well be identical with the enzyme aminopolypeptidase that has been purified and investigated by him. Concentrated enzyme preparations were used as a source of intrinsic factor and incubated with beef muscles that had been predigested with pepsin. This preparation seemed to be active. Control experiments were performed on 2 patients with only aminopolypeptidase without beef. In one case the effect as regards reticulocytes and bone-marrow was negative. The serum iron possibly dropped somewhat. The effect of later peroral doses of folic acid was excellent. In the second case there was a definite drop of the serum iron and an irregular increase in

reticulocytes with a normoblastic reaction in the bone marrow. There was no secondary effect of folic acid as regards reticulocytes, but there was a good increase in erythrocytes and hemoglobin. The results tend to show that the enzyme preparation may be active without the presence of extrinsic factor. The authors point out that further experiments are necessary.

J W

ON THE CURATIVE EFFECT OF PURE DUODENAL SECRETION FROM SWINE IN CASES OF PERNICIOUS ANEMIA
E. Landboe-Christensen and C. L. S. Bohn From the Department of Anatomy, Faculty of Medicine, University of Copenhagen. *Acta Med Scand* 127: 116-129, 1947

The authors studied the effect of the juice from a duodenal pouch in swine. This is regarded as the only way of avoiding contamination with gastric secretions. One patient got 150 ml duodenal juice daily for two weeks. Some pepsin and some HCl were added. The food of the patient was not controlled. There was no immediate increase in reticulocytes but the second response to desiccated stomach also gave very poor results. In the second case 150 ml pure duodenal juice was given with a noncontrolled food intake for ten days. The reticulocyte response was quick and marked. The bone marrow changed from megaloblastic to normoblastic. Liver extracts gave no secondary reticulocyte reaction. The authors conclude that an antipernicious-anemia-factor is present in the duodenal secretion from swine. They point out that there may be differences between the conditions in man and in animals.

It seems to the reviewer that the effect of purified aminopolypeptidase solutions mentioned in the previous paper and the effectiveness of pure duodenal juice should be further investigated as it may give a clue to the real nature of Castle's principle.

J W

ANEMIE HYPERCHROME AVEC MEGALOCYTES, REFRACTAIRE A L'HEPATOTHERAPIE. ACHRESTIC ANEMIA
E. F. J. H. Galger From the Clinique Medicale de l'Hôpital St Jan, Zaandam, Holland. *Acta Med Scand* 126: 505-527, 1947

There has been considerable discussion about the real nature of achrestic anemia as described by Wilkinson and it seems as if most continental hematologists regard it as a type of aplastic anemia that has nothing to do with pernicious anemia. The recent successful treatment of such liver refractory cases with folic acid gives this problem more than academic interest. The author is of the opinion that these cases have a really megaloblastic bone marrow in spite of the presence of hydrochloric acid in the gastric juice. There were no symptoms from the nervous system. Potent liver extracts gave no reticulocytosis and no drop in the serum iron. Big transfusions were necessary. Nicotinic acid and yeast extracts were not of any help in the first case. The second one developed anemia during her pregnancy. After delivery the anemia progressed and was not influenced by large doses of different liver extracts. Later there was found an irregular rise in reticulocytes and there was a slow improvement of the blood values. After one year there was still a definite macrocytic anemia but the megaloblastic bone-marrow had become normal. In both cases it seems as if the gastric juice would have been free from intrinsic factor.

Possibly these cases might respond to treatment with folic acid.

J W

PERNICIOUS ANEMIA IN CHILDHOOD. II. RESPONSE TO FOLIC ACID. *J. C. Peterson* From the Department of Pediatrics, Vanderbilt University School of Medicine, Nashville, Tenn. *Am J Dis Child* 73: 578-580, 1947

The author gives a brief follow-up report on a previously described (*Am J Dis Child* 71: 252-268, 1946) case of pernicious anemia in a 6 year old girl whose history of anemia dated back to the age of 8 months. There was maximal response to administration of liver extract, but continuous therapy was required to maintain a remission. From 1940 to 1946 she was observed during the course of five relapses, some specifically induced by withdrawal of treatment. During such a relapse in 1946 she was given 5 mg of folic acid orally twice daily. The response to folic acid was similar to that previously observed following the administration of liver extract.

L E Y

THE CLINICAL MANIFESTATIONS OF SICKLE CELL ANEMIA. *V. Grover* Brooklyn, N. Y. *Ann Int Med* 26: 843-851, 1947

This article, which tabulates the signs and symptoms of 48 patients with sickle cell anemia, provides useful data as to the incidence of these various manifestations. Of interest is the height of fever (although

it is not clear whether this is related to incurrent infection or to the sickle cell disease), the frequency of pain in the lower extremities and abdomen, the leg ulceration observed in 25 per cent of the cases, the presence of mental deficiency in 7 cases, and various cardiac manifestations. The authors also remark on the rapid change in size of the spleen and liver over a number of days.

C A F

LIPID METABOLISM AND DEVELOPMENT OF ANEMIA IN SPLENECTOMIZED GUINEA PIGS FED CHOLESTEROL

B Kennedy and R Okey From the Department of Home Economics, University of California, Berkeley
Am J Physiol 149 1-6, 1947

Guinea pigs fed diets containing 1 per cent cholesterol and 15 per cent fat develop, in chronologic order, fatty livers rich in cholesterol, splenomegaly, and severe anemia in which the red cells are both excessively fragile and excessively resistant to hypotonic solutions. The resulting syndrome is a hemolytic anemia and includes anemia, hyperbilirubinemia, bone marrow hyperplasia, pigment gallstones, and hemosiderosis. This disease is frequently cured by splenectomy. The authors wondered whether the anemia could, therefore, be due to the splenic hyperplasia, *c g*, an enlarged spleen excessively destroying red cells.

They therefore first splenectomized guinea pigs and then, after a control period of waiting, fed them cholesterol and fat. The resulting animals lost weight and developed anemia with hemolysis just as the original guinea pigs. The liver and blood lipids, and the incidence of gallstones, were identical in splenectomized and intact guinea pigs. The conclusion was therefore reached that the spleen was not primarily responsible for the anemia.

A parallel may be drawn to the congenital spherocytosis of human beings, in which splenectomy, by removing the chief site of red cell destruction, 'cures' the hemolytic syndrome, although the fundamental aberration (spherocytosis) remains. It seems more than ever advantageous to divide hemolytic anemias into three types: (1) intrinsic defects of the red cells, making them especially vulnerable to the normal action of the spleen, (2) action of demonstrable or nondemonstrable plasma or tissue substances on originally normal red cells (*c g*, circulating agglutinins). The guinea pig anemia probably fits best here. Such damaged red cells are also particularly liable to destruction, especially in the spleen, and (3) excessive destruction of normal red cells by a hyperactive spleen (hypersplenic hemolytic anemia). In all three types, splenectomy may be curative, but it is only in the relatively rare third category that the spleen is fundamentally responsible for the disease.

S E

THE USE OF FOLIC ACID IN SPRUE *R M Suárez, T D Spies, and R M Suarez, Jr* From the School of Tropical Medicine of Puerto Rico, San Juan Puerto Rico, and the University of Cincinnati, Cincinnati, Ohio. Ann Int Med, 26 643-677, 1947

This is a comprehensive report on the management of 50 cases of tropical sprue with folic acid. Twenty-two cases were acute and severe. These cases were thoroughly studied with sternal marrow differential counts, complete hematologic studies of the peripheral blood, blood chemistries, gastric analyses, stool urobilinogen, and the fat content and fat partition of the stools. Of particular interest are the changes in stool, glucose tolerance tests and hematologic picture after treatment. Admission stools on 12 patients averaged 19.18 per cent solid material in fresh feces, 26.46 per cent total fat in dried feces, 79.31 per cent free fatty acids and 85.22 per cent of total split fats. A few days after treatment the solid content of feces was 13.19 per cent, and there was 20.76 per cent total fat in dried feces, 67.33 per cent being free fatty acids and total split fat being 72.75 per cent. (Normal values for solids 25.23 per cent, total fats in dried feces 21.23 per cent, free fatty acids 66.77 per cent, and total split fat 72.28 per cent.) Oral glucose tolerance tests before treatment showed an increase in blood sugar of between 1 and 32.5 mg per cent. After 1 to 2 months treatment all but 2 showed improvement and 6 of 14 showed a rise of greater than 40 mg per cent.

Ten cases were summarized with a discussion of reticulocyte and red cell responses to varying doses of folic acid. The patients were maintained on either a diet poor in proteins or a sprue diet rich in these materials. On the poor diet hematologic response was submaximal even with doses up to 100 mg of folic acid. With an adequate diet a daily dose of 20 mg of folic acid by mouth gave a good initial response. The authors state that the patients are maintained on as little as 2½ to 5 mg per day. Follow-up on these patients extended over only 1 to 4 months.

SYNTHETIC FOLIC ACID THE EFFECTIVENESS OF A CONJUGATED FORM IN THE TREATMENT OF TROPICAL SPRUE, ADDISONIAN PERNICIOUS ANEMIA AND NUTRITIONAL MACROCYTIC ANEMIA *T D Spies, G G Lopez, F Mslanes, and T Aramburu* From the University of Cincinnati at Hillman Hospital, Birmingham, and the Calixto Garcia Hospital and the University of Havana, Cuba *J A M A* 134 18-22 1947

This is another report on the clinical efficacy, in the treatment of macrocytic anemias, of compound similar chemically to folic acid. To date, these substances can be classified into three groups (1) pteroyl glutamic acid, which is the compound found in liver L casei factor, in yeast L casei factor, and vitamin B₁₂, (2) pteroyl-diglutamyl glutamic acid, which is the fermentation L casei factor, and (3) pteroyl hexaglutamyl glutamic acid, which is the "vitamin B₁₂ conjugate" material. The chemical difference among these substances lies in the number of glutamic acid residues per molecule.

The present report relates the response of patients with macrocytic anemias to pteroyl-diglutamyl glutamic acid, with the usual reticulocytosis and subsequent clinical and laboratory improvement similar response to pteroyl-glutamyl glutamic acid (2 glutamic acid residues) has previously been published (T D Spies, R E Stone, and R L Toca, *South Med J* 40 175-6, 1947).

The authors suggest that the more complicated chemical compounds, such as the hexaglutamyl compound of vitamin B₁₂ conjugate, may be broken down with difficulty by some patients with macrocytic anemias. The relative efficacies of these and other similar compounds may ultimately help to elucidate their manner of action in pernicious anemia, and perhaps to discover an ideal substance for clinical use.

S E

THE BLOOD PICTURE AND PLASMA PROTEIN LEVEL FOLLOWING INJURY *J Vaughan, M Thomson and M Dyson* From the N W London Blood Supply Depot, London, England *J Path & Bact* 58 749-765 1947

Under very trying war-time conditions the three groups of patients studied consisted of (1) accident other than those due to enemy action, (2) industrial accidents in which superficial burns were associated with fractures, and (3) accidents due to enemy action. The results of the various determinations showed that both erythrocyte and hemoglobin values fall during the first week and then rise to a higher level. Reticulocytes were low immediately following the injury, but rose to the upper limit of normal immediately preceding the rise in hemoglobin. The elevated sedimentation rate was very likely due to the increased plasma fibrinogen. Although the leukocytes decreased slightly during the period of observation, they remained within normal limits. Leukopenia was not encountered.

O P J

THE EFFECT OF DIFFERENT DIETS AND OF IRON MEDICATION ON THE NUTRITIONAL ANEMIA OF INDIAN ARMY RECRUITS *M Hynes, M Ishaq, and O P Verma* From the Anemia Investigation Team, Medical Directorate, General Headquarters, India. *The Indian J M Research* 34 273-288, 1946

In a preceding report this team of investigators had shown a correlation between the presence of anemia and evidence of malnutrition as indicated by muscular development and dermal and ocular signs of vitamin deficiency. There was found to be a direct correlation between the hemoglobin level and the cell volume and mean corpuscular hemoglobin concentration so that all severe or moderately severe anemias were microcytic and hypochromic. It was noted that the amount of hookworm infection could be correlated with the severity of the anemia in only the more malnourished third of the recruits.

During the first six months after induction there was a rise in the hemoglobin level in the group that was given the army diet alone, but the most severe anemias did not reach a normal level at the end of six months. It was found that three grains of ferrous sulfate daily cured all the anemias at the end of four months and was judged to be as effective as six grains daily. The rate of hemoglobin rise was less in both the treated and control group if milk was substituted for meat as the source of protein in the diet. It was found that hookworm infection did not interfere with the rate of hemoglobin regeneration but that septic infections of the areolar tissue, tonsillitis and malaria depressed hemoglobin regeneration. This is an excellently controlled mass study of the effect of iron therapy and gross alterations in the diet on hemoglobin regeneration in human subjects.

LES MALADIES ERYTHREMIQUES (ERYTHREMIC DISEASES) *G. Di Guglielmo*, Directeur de l'Institut de pathologie spectrale de Naples (Italy) *Rev. Hémat.* 1: 355-398, 1946

This important study is founded on 80 observations of erythremia (Erythroleukemia) most of them published in Italy and in particular by Di Guglielmo who was the first to describe the disease in 1917.

The author defines the disease as follows: Generalized primitive proliferation of the erythroblastic series, which may be acute or chronic, occur in all ages without sex preference. The acute form, the less rare, was the first to be known. The symptoms are the following: Anemia, fever, splenomegaly and hepatomegaly. In the blood young erythroblasts are seen, which is often atypical, and there is in the erythropoietic center an embryonic proliferation of erythroblasts. The evolution lasts only a few weeks. The chronic form is also marked by anemia and hepato-splenomegaly, but the erythroblasts found in the peripheral blood are more mature forms. The duration of this form is about two years.

In both forms, the anemia is a constant feature, and always severe. The mechanism is complex: lack of formation of normal erythroblasts and increased destruction of abnormal red cells in peripheral blood. The author supplies rich pathologic material from biopsies and postmortem examinations (illustrated by 28 microphotographic and color plates). There is a striking erythroblastic proliferation and an important reticulo-endothelial proliferation in the bone marrow, lymph nodes, liver, and also in the kidneys, heart, pancreas, and adrenals. A complete bibliography terminates this weighty study.

J P S

INHERITED DISORDERS OF THE BLOOD IN RODENTS *H. Grüneberg* *Proc. Roy. Soc. Med.* 40: 191-192, 1947

The author of this short note has done a large amount of work on hereditary mechanisms of various anemias in the rat and the mouse. Most of the work is not obviously related to clinical mechanisms, but relationships between certain of these disorders and certain anemias in man have been suggested.

Seven disorders are discussed by Grüneberg. Among these several are of special interest. Siderocytic anemia of the mouse is associated with a recessive gene for certain other characteristics, the characteristic finding is the presence of nonhemoglobin iron in the erythrocytes. Grüneberg conceives of these cells as aged cells, counterparts of the reticulocytes, and notes that they are present in various human hemolytic anemias in proportion to the severity of the hemolysis.

A lethal spherocytic anemia occurs as a recessive characteristic in the rat which Grüneberg attributes to a faulty marrow which produces red cells of inferior quality, whose survival time in the circulation is reduced. This anemia is not analogous to familial spherocytosis of human beings. A second form of familial hemolytic anemia, however, occurs as the recessive acholuric jaundice of the rat. Homozygotes have microcytosis, increased hypotonic fragility, jaundice, and splenomegaly. Heterozygotes may show no abnormality, or may show increased hypotonic fragility and reticulocytosis without jaundice. The possible relationship of this disorder, whose heredity has been worked out, to familial spherocytosis of humans is intriguing. The disease in the rat, however, is not cured by splenectomy, so that a definite parallel cannot be drawn.

As in other fields in medicine, study of disorders occurring in animals breeding under controlled laboratory conditions may be expected to shed light on similar disorders in the clinic. The use of known hereditary mechanisms in rodents to elucidate the mechanisms of similar human disorders is another line of attack in these still puzzling problems.

S E

HAEMOLYTIC ICTERUS (ACHOLURIC JAUNDICE), CONGENITAL AND ACQUIRED *J. F. Loutit and P. L. Mollison*

From the South London Blood Supply Depot, London, England *J. Path. & Bact.* 58: 711-728, 1947

Hemolytic anemias have been the center of much controversy ever since they were first studied. The present article contains evidence which indicates that congenital and acquired cases of hemolytic icterus are both physiologically and serologically different from each other. They are two etiologically different conditions within the syndrome of acholuric jaundice. Some of the evidence in support of this belief is that when normal blood is transfused to recipients with the congenital type of anemia, the survival of these cells is from 100-120 days. But when recipients with the acquired type of anemia are transfused with normal blood, the survival of the cells is markedly reduced. In addition to this, when washed red cells from cases of congenital acholuric jaundice are tested for agglutination with anti-human-serum serum they are not agglutinated, but cells from cases of acquired acholuric jaundice readily agglutinate. Loutit

and Mollison believe that the congenital type of hemolytic icterus is due to a hereditary defect of the erythroid elements and that in the acquired type an abnormal hemolysin co hemolysin system is in action

O P J

FURTHER STUDIES ON THE RELATIONSHIP BETWEEN CELL PERMEABILITY AND METABOLISM THE EFFECT OF CERTAIN RESPIRATORY INHIBITORS ON THE PERMEABILITY OF ERYTHROCYTES TO NON-ELECTROLYTES *F R Hunter* From the Department of Zoology, University of Oklahoma, Norman, Oklahoma *J Cell & Comp Physiol* 29 301-312, 1947

The purpose of the experiments reported in this paper was to determine whether or not selective permeability depends on energy derived from metabolic activities within the cell. For this purpose beef and chicken blood was used. Substances, such as potassium cyanide, sodium fluoride, arsenious oxide and iodoacetate, which interfere with metabolic activities, were allowed to act on blood corpuscles at $37^{\circ} \pm 0.1^{\circ} \text{C}$ for varying periods of time. Although metabolic systems were sensitive to these substances and inhibited by them, there was not a change in the permeability. Apparently the permeability of the erythrocyte to non-electrolytes does not depend on energy derived from either aerobic or anaerobic metabolism.

O P J

THE EFFECT OF WASHING ON THE PERMEABILITY AND METABOLISM OF CHICKEN ERYTHROCYTES *F R Hunter* From the Department of Zoology, University of Oklahoma, Norman, Oklahoma *J Cell & Comp Physiol* 29 313-321, 1947

In the previous paper, metabolic activities of erythrocytes were inhibited by the addition of various substances. In the present paper, similar activities have been influenced by removing certain components of the enzyme-substrate by washing chicken erythrocytes three or four times with Ringer-Locke solution. In so doing, anaerobic glycolysis was reduced to an immeasurable level. Unhemolyzed cells were present after they had been exposed to anaerobic conditions for as long as 384 hours. In these experiments, it was necessary to avoid contamination with hemolytic bacteria. The results of these experiments show that permeability of the chicken erythrocyte to glycerol does not depend on energy derived from cell metabolism.

IMMUNOHEMATOLOGY

DEMONSTRATION OF ANTIBODIES IN ACQUIRED HEMOLYTIC ANEMIA WITH ANTI-HUMAN GLOBULIN SERUM *R S Evans, R T Duane and V Behrendt* From the Department of Medicine, Stanford University School of Medicine, San Francisco, Calif *Proc Soc Exper Biol & Med* 64 372-375, 1947

The Coombs test which determines the red cell agglutinating effect of serum from rabbits immunized against human serum globulins, was applied with positive results in two cases with acquired hemolytic anemia, indicating the presence of an adsorbed immune body type of hemolytic agent attached to their erythrocytes. Normal blood transfused into these patients shared in the hemolytic process, presumably as a result of exposure of the donor cells to, and their adsorption of, a hemolytic agent present in the circulation of the recipients. It was not possible to demonstrate any hemolytic properties, or adsorbable antibodies in the serums of these patients, which may be explained on the basis of a continuous excess of antigen provided by the circulating red cell mass. Support for this thesis was obtained from experiments in which the immune substance, probably the active anti-red cell antibody, was eluted in warm saline from the affected red cells of the patients, and then combined, *in vitro*, with normal cells.

C P E

ÉTUDE SUR L'ICTÈRE HÉMOLYTIQUE EXPERIMENTAL PAR INJECTION ET INGESTION D'ANTISÉRUM (STUDY ON EXPERIMENTAL HAEMOLYTIC JAUNDICE, BY ANTISERUM INJECTION OR INGESTION) *M Bessis and P Fréixa* Laboratoire de Recherches du Centre National de la Transfusion Sanguine (Paris) *Rev Hemat* 2 114-146, 1947

The injection of anti-red cell serum into the rat provokes an acute syndrome with hemoglobinuria, an acute hemolytic anemia, or a subacute curable anemia. These experiments with rats bring confirmation

to the Dameshek and Schwartz experiments with guinea pigs, and also show that increased osmotic fragility and microspherocytosis is easily induced. The personal contribution of the authors is as follows:

1. In a fresh preparation of red cells one notes a pseudo-agglutination of the spherocytes instead of normal rouleaux-formation. There are some spindle-shaped red cells and numerous erythroblasts. In the acute cases hemoglobin crystals may be seen in the cells.

2. There is a marked leukocytosis with a histiocytic reaction and many leukocytes show erythrophagocytosis. Jaundice was present in subacute or acute form and when it was especially severe erythrophagocytosis was striking.

3. The histologic findings in liver, spleen, and kidneys are identical with those found in hemolytic disease of the human new-born, but nuclear jaundice was not encountered.

4. The crucial antibody was found on the red cells of the injected animal (conglutination method).

5. The peroral administration of the anti-serum to the new-born rats induces trouble only if it has been given before the twentieth day.

The authors discuss the relationship between this experimental anemia and the human erythroblastosis of the new-born. This weighty study is illustrated with numerous microphotographs and colored plates (18 pictures).

J P S

INHIBITION BY CERTAIN POLYSACCHARIDES OF HEMAGGLUTINATION AND OF MULTIPLICATION OF INFLUENZA

VIRUS R. H. Green and D. W. Woolley. From the Laboratories of the Rockefeller Institute for Medical Research, New York, N. Y. *J. Exper. Med.* 86: 55-64, 1947.

The complex carbohydrates, apple pectin, citrus pectin, flaxseed mucilage, blood group A substance, gum acacia and gum mirth, as well as an aqueous extract of chicken erythrocytes, were shown to inhibit the agglutination of chicken red cells by the PR8 strain of influenza A virus. Many, but not all, of the inhibitory substances were polysaccharides rich in galacturonic acid. Alginic acid, a polysaccharide largely composed of mannuronic acid units, was inactive, as were the simple carbohydrates such as galactose, galacturonic acid and aldobionic acid. Detailed study of the action of apple pectin showed that this substance affected both virus and red cell and that it also inhibited the multiplication of virus in embryonated eggs.

These observations serve well to illustrate the usefulness of the erythrocyte as a tool for the study of virus-cell relationships. The results obtained also illustrate how antagonism between structurally similar compounds may be used as a guide in investigating the biology of viruses.

L E Y

THE NATURE OF NON-SPECIFIC INHIBITION OF VIRUS HEMAGGLUTINATION W. F. Friedwald, E. S. Miller, and L. R. Whatley. From the Department of Bacteriology and Immunology, Emory University School of Medicine, Atlanta, Georgia. *J. Exp. Med.* 86: 65-75, 1947.

Saline extracts of lung, liver, kidney and spleen from human beings, rabbits and guinea pigs were found to inhibit hemagglutination by mumps virus and by the PR8 and Lee strains of influenza virus. The inhibition titers of organ extracts were usually higher than the titers obtained with sera from the corresponding animals.

Saline extracts of human and chicken erythrocytes also contained an inhibitory substance in high titer, and these cells were markedly agglutinated by influenza and mumps viruses. Rabbit cells were not appreciably agglutinated by these viruses and extracts of rabbit cells were not inhibitory. Sheep red cells varied in their capacity to agglutinate and also in their yield of inhibitory substance. When the virus receptor substance was removed from chicken cells by adsorption and elution with influenza virus, extracts of the cells were no longer inhibitory.

Evidence is presented that the inhibitory substance is not an antibody and that it is distinct from the blood group factors A, B, and Rh. The findings with the virus inhibitory substance are, nevertheless, compared by the authors to those with A and B factors. Both are found in many types of mammalian cells in addition to erythrocytes and also in various body fluids. The A and B factors, moreover, may combine with isoantibodies to inhibit hemagglutination.

Failure of the inhibitory substance to neutralize influenza virus *in vivo* suggests that it is not an important factor in preventing infection. On the contrary, it is postulated that it may actually have a deleterious effect in human infections by preventing union of virus with antibody.

A recent paper by Bovarnick and de Burgh (*Science* 105 550-551, 1947) should also be cited here. These authors prepared lipid extracts of erythrocytes which inhibited agglutination of these cells by influenza and mumps viruses.

L E Y

THE INCIDENCE OF THE "DANGEROUS" GROUP O DONOR. RESULTS OF THE TITRATION OF ONE THOUSAND CONSECUTIVE SERA. *A. Zoutendijk*. From the South African Institute for Medical Research, Johannesburg. *South African M. J.* 21 438-441, 1947.

Sera from 1000 unselected European group O donors were titrated at 37°C with 2 per cent suspensions of fresh A and B cells. End points were read grossly after incubation for one hour and titers were expressed in terms of the dilution of serum itself and not of the final mixture of serum and cell suspension.

Taking a titer of 1/200 as 'dangerous,' 221 of the donors tested were classified as unsafe for transfusing patients belonging to groups other than O. Of these, 95 had high anti-A titers only, 62 had high anti-B titers only, and 64 of the 221 donors had both high anti-A and anti-B titers. The incidence of high titers is considerably lower in the experience of other investigators, probably due mainly to differences in technique.

The author urges that use of the term, 'universal donor,' be discontinued because it gives a false sense of security. He further recommends that all group O donors be classified according to isoagglutinin titer—a task which is considered reasonable since variations in titer from time to time are small in healthy persons. This procedure is preferred to that of adding A and B group specific substances to O blood prior to transfusion to A, B, or AB recipients.

Although no attempt is made in this paper to discuss the controversial issues involved in the use of universal donors, a timely warning is given.

L E Y

FALSE POSITIVE TESTS FOR SYPHILIS. A STUDY OF THEIR INCIDENCE IN SPOROZOITE-INDUCED VIVAX MALARIA. *C. R. Rein and J. F. Kent*. From the Division of Serology, Army Medical School, Washington, D. C. *J. A. M. A.* 133 1001-1003, 1947.

Ninety volunteers were inoculated with *P. vivax* sporozoites in order to study the treatment of the disease. A battery of seven diagnostic tests was done for syphilis, including, in addition to the usual tests, a special test with cardiolipin antigen devised by Rein and Bossack. The following results were obtained:

1. 63.3 per cent of the subjects developed false positives with one or more tests at some time during the course of the malaria.

2. In no instance was there a positive test before the fever or the parasitemia.

3. The false positive test appeared on the average a little over eight days after the parasitemia (range 0-30 days).

4. The false positive test was usually transitory and of low titer. Its duration after a given attack of malaria was from 2 to 98 days, although in one patient who had successive relapses the false positive serologic reaction was present for 517 days.

5. The Kahn standard tests gave the most false positives. The Hinton flocculation test gave the least false positives. The new Rein-Bossack cardiolipin test, a microfloculation procedure, was also seldom falsely positive.

S E

PATHOGENESIS OF PASSIVE RH ISOSENSITIZATION IN THE NEWBORN (ERYTHROBLASTOSIS FETALIS). *R. R. Darrow and J. Chapin*. From the Women and Children's Hospital, Chicago, Ill. *Am. J. Dis. Child.* 73 257-278, 1947.

The authors advance the hypothesis that Rh antibodies produced as a result of isoimmunization during pregnancy are of two types: erythrocyte-destroying antibodies and sensitizing antibodies. The former act upon the infant's Rh-positive erythrocytes in such a way that their destruction by phagocytosis is greatly accelerated. The sensitizing antibodies, according to the concept presented, exert their effect within tissue cells by reacting with Rh antigen freed by the destruction of Rh-positive erythrocytes. The intracellular reaction injures the cell and causes the release of histamine and possibly other toxic substances into the circulation. These substances may then have a damaging effect on susceptible tissues elsewhere in the body.

It is emphasized that maternal antibodies are carried first to the fetal liver, and that hepatic cells suffer most from the sensitization reaction. Jaundice due to rapid destruction of erythrocytes is intensified by hepatocellular injury, and liver damage is also held at least partly responsible for hemorrhagic diatheses and hypoproteinemia. Edema is attributed to hypoproteinemia and increased capillary permeability, the latter being caused by direct sensitization of the endothelium or by the action of histamine produced in organs such as the liver and lung. It is further suggested that histamine may be responsible for the development of pulmonary edema in the newborn and also for intrauterine asphyxia as a result of placental edema. Possible causes of brain injury are anoxia, intoxication (histamine) and direct sensitization of nuclear neurons. Kernicterus is attributed to the increased avidity of affected cells for bilirubin.

Three of the 5 erythroblastotic infants described were transfused with Rh-positive blood. It is suggested that the favorable results obtained were due in part to the 'desensitizing' action of the Rh-positive cells.

The speculations set forth in this paper are supported to only a limited extent by the authors' personal observations. They should, nevertheless, serve to stimulate further investigation of hemolytic mechanisms, of the much-debated 'toxic' effects of rapid red cell destruction, and the merits of exchange transfusions. Until more is known concerning the pathogenesis of erythroblastosis fetalis, most clinicians will probably prefer to continue their current practice of transfusing affected infants with Rh-negative blood.

L E Y.

LÉSIONS DU SYSTÈME NERVEUX CENTRAL DANS DEUX CAS D'ICTÈRE NUCLÉAIRE DU NOUVEAU-NÉ—(CENTRAL NERVOUS SYSTEM INJURIES IN TWO CASES OF NUCLEAR JAUNDICE IN NEWBORN) *Ivan Bertrand* (Paris)
Rev d hemat 1 399-420, 1946

The author makes a minute study (topographic and histologic) of two cases of nuclear jaundice due to Rh immunization. His conclusions are the following:

There is a very important extension of the histologic lesions which largely exceeds the macroscopic topography of the biliary impregnation. There is an edematous infiltration of nervous elements and also of the perivascular areas. The neuroganglionic degeneration is characterized by acute tumefaction, liquefaction, and *Schwererkrankung* of Nissl. The cerebral cortex, the paraventricular nuclei of the cerebral trunk, the olives bulbaires and the *noyau dentelé* are the more affected areas. All these lesions are degenerescences without much satellitic reaction (16 pictures and microphotographs).

J P S

AUTOHEMAGGLUTINATION AND RAYNAUD'S PHENOMENON *G B Forbes* Brit M J 1 598-600, 1947

The literature dealing with cold agglutinins is briefly reviewed. Eighteen published case reports of the association of autohemagglutination with peripheral vascular phenomena simulating Raynaud's disease are cited. The author presents clinical and laboratory studies of a case with symptoms of Raynaud's disease caused by the presence of an autohemagglutinin activated by exposure to cold. The titer of this agglutinin was 1,024. There was no predisposing disease to account for the development of this agglutinin.

J F R

HEMOLYTIC TRANSFUSION REACTIONS *M J Nicholson* From the Department of Anesthesiology, Lahey Clinic, Boston, Mass. Lahey Clin Bull 5 101-113, 1947

The author presents a concise review of the subject and properly stresses the importance of (1) clerical errors, (2) masking effect of anesthesia, (3) examinations for presence of hemoglobinemia and hemoglobinuria, and (4) recheck of crossmatch with fresh specimens from donor and recipient.

Of particular interest with regard to therapy is the reference to Diamond's suggested administration of A and B group specific substances to group O patients who have been transfused with group A or group B blood. The object of this procedure is to neutralize the alpha and beta agglutinins in the recipient's serum and thus delay the destruction of remaining transfused incompatible cells.

A case is reported in which a group O Rh positive male was given 500 cc of group A Rh positive blood. The patient made a satisfactory recovery following administration of alkali, group O blood and 40 cc of a solution of A and B factors.

L E Y

LEUCOCYTES AND LEUCOCYTIC DISEASE

ALEUKEMIC MYELOSIS CHRONIC NONLEUKEMIC MYELOSIS, AGNOGENIC MYELOID METAPLASIA, OSTEOSCLEROSIS, LEUKO-ERYTHROBLASTIC ANEMIA AND SYNONYMOUS DESIGNATIONS *E L Heller, M G Lewisohn and W E Palm* From Department of Pathology, University of Pittsburgh and the Presbyterian Hospital, Pittsburgh, Pa *Am J Path* 23 327-365, 1947

It is well known that patients with myelogenous leukemia may differ markedly from one another with respect to their quantitative as well as their qualitative blood pictures. There has been a question as to whether or not some cases are permanently aleukemic. The present article reviews the literature and offers 3 new cases in support of the thesis that there is a disease, aleukemic myelosis, which is fundamentally leukemic in nature. The peripheral blood may contain immature myeloid cells but not in the same degree as a frank leukemia. On the other hand, it may not present a leukemoid reaction. Tissue responses in these patients have been interpreted to indicate a local origin of leukemic cells from the reticulo-endothelial system rather than a metastatic one.

O P J

THE FURTHER EFFECT OF LEUKOCYTOSIS—PROMOTING FACTOR OF EXUDATES WHEN INJECTED IN CONNECTION WITH INFLAMMATION *V Menkin* From Chase Foundation for Cancer Research, Temple University School of Medicine, Philadelphia, Pa *Arch Path* 43 566-569, 1947

This is a continuation of the many studies on inflammation which the author has been conducting in recent years. When dogs were caused to develop acute pleurisy by intrapleural injections of turpentine, the leukocyte count returned to normal in about one day. The leukocyte count responded in a similar manner when single intravascular injections of leukocytosis-promoting factor were administered to healthy dogs. But when leukocytosis-promoting factor was administered to dogs with an acute pleurisy, the leukocyte count reached a higher level and remained there for about nine days. The clinical implications are that natural leukocytosis might be reinforced even during antibiotic therapy.

O P J

GLYCOGEN CONTENT OF ISOLATED WHITE BLOOD CELLS IN GLYCOGEN STORAGE DISEASE *R Wagner* From The Boston Floating Hospital and the Department of Pediatrics, Tufts College Medical School, Boston, Mass *Am J Dis Child* 73 559-564, 1947

The glycogen concentration in whole blood, plasma, red cells, and in isolated leukocytes was determined repeatedly in a case of the hepatic form of glycogen storage disease (von Gierke's disease). In no case could glycogen be demonstrated in the erythrocytes. Glycogen determinations in whole blood were considered unsatisfactory technically and of limited diagnostic value. In contrast to the plasma of normal persons, which was always found free of glycogen, the plasma in the case described contained 8.7 to 15.6 mg per 100 cc. Determinations of glycogen in isolated leukocytes were considered of greatest diagnostic value. In normal blood the granulated white cell, which is the only carrier of glycogen, was calculated to contain this substance in an average concentration of 4.23 micrograms per million cells. In the case of glycogen storage disease studied, the range of glycogen concentration per million adult polymorphonuclear cells was 2.7 to 7.4 times greater than in normal leukocytes. Evidence is cited that granulocytes are incorporated in the system of tissues serving carbohydrate metabolism.

L E Y

THE EFFECT OF AGE ON THE LEUKOCYTE COUNT. A COMPARISON OF WHITE BLOOD CELL COUNTS IN AGED AND YOUNG INDIVIDUALS, WITH SPECIAL REFERENCE TO THE RESPONSE TO INFECTION *W R Galbert, L W Hutaff, and G T Harrell* From the Bowman Gray School of Medicine, Winston-Salem *Geriatrics* 2 96-100, 1947

Since aging results in a deterioration of various systems of the body, a wearing-out process might be expected in the bone-marrow with resultant changes in the values of the circulating blood elements. It might also be expected that changes in the white blood cells might interfere with the anti-infective powers of the patients. This article reports hematologic studies on hospitalized patients of various ages, with analysis of the counts for various age groups.

It was found that the mean white blood count was the same at various ages from 20 to 49 as after the

age of 50 years. It was found also that the response of the white cell count to infection was the same in all decades. These negative results suggest that there is little "wearing-out" of the hematopoietic system in the course of the usual adult life.

S E

INFECTIOUS MONONUCLEOSIS. AN AUTOPSY REPORT *F H Allen, Jr and A Kellner* From the Blood Grouping Laboratory, Children's Hospital, Boston. *Am J Path* 23: 463-477, 1947

Although Downey and his associates have divided the leukocytoid lymphocytes found in infectious mononucleosis into three main types, it has long been recognized that there is considerable pleomorphism within a given category. The qualitative blood picture not only varies among individuals but also within a given patient, depending upon the severity and stage of the disease. In like manner, the clinical features of this disease have been characterized as protean. The present article deals with the autopsy findings in a 23 year old American Army Air Forces pilot, who was killed in an accident following a previous acute illness. The diagnosis was established by the clinical picture, hematologic findings and strongly positive heterophil antibody tests. At autopsy focal cellular infiltrations were found in the liver, kidneys, heart, lungs, adrenals, testes and brain. From this it became apparent that infectious mononucleosis is a generalized disease with changes in almost every organ in the body.

O P J

SPONTANEOUS RUPTURE OF THE SPLEEN DUE TO INFECTIOUS MONONUCLEOSIS *J M Sullivan and S E Wasserman* From the Veterans Hospital, Wood, Wisconsin, and the Marquette Univ. School of Medicine, Milwaukee, Wisconsin. *J A M A* 134: 144-145, 1947

An additional case of rupture of the enlarged spleen of infectious mononucleosis is reported. The patient was a 25 year old man whose immediate complaints were headache, malaise, weakness, sore throat, and upper abdominal pain. Before admission to the hospital, the patient had sudden agonizing left upper quadrant pain followed by fainting, and several days later developed tenderness and rigidity in the left upper quadrant, pain in the left shoulder, and signs of consolidation or fluid at the left chest. The liver and spleen were not palpable. A blood count was normal. Exploration revealed 1500 cc. of free blood in the abdomen, and two lacerations of the spleen with corresponding subcapsular hematomata. The spleen showed only hyperplasia (weight 695 grams). Blood studies showed abnormal cells on only one occasion, but the heterophile antibody test was positive in a dilution of 1:248 six days after operation. The patient did well.

The authors note that 12 cases of such rupture have been reported from 1944 to 1946.

S E

BLOOD COAGULATION AND HEMORRHAGIC DISEASES

THE INTERACTION OF PROTHROMBIN A AND B *F L Munro and M P Munro* From the Department of Medicine, Jefferson Medical College and Hospital, Philadelphia, Pa. *Am J Physiol* 149: 95-99, 1947

Quick's hypothesis that prothrombin is a complex consisting of two substances, prothrombin A and prothrombin B, has been accepted by many workers, although it has been violently negated by others, who believe that prothrombin A is merely plasma fibrinogen (E C Loomis and W H Seegers. *Am J Physiol* 148: 563-567, 1947). The present authors, working on Quick's hypothesis, found that hepatectomy in the dog was followed by a reduction in both the A and B components, and that an excess of either could partially compensate for a deficiency in the other.

They therefore studied mixtures of plasmas artificially so modified as to contain large amounts of either prothrombin A or B, respectively. In such mixtures, where from 0 to 100 per cent of the A plasma was added to 100 per cent to 0 per cent of the B plasma respectively, they found that an increase in the prothrombin time appeared only when the concentration of prothrombin A was over 5 per cent and that of prothrombin B under 50 per cent, or when prothrombin B was over 70 per cent and A less than 10 per cent. In other combinations, the two plasmas were mutually complementary. The conclusion was reached that a given clinical prothrombin time might be the result of varying degrees of deficiency of each complex, but that the exact nature of the abnormality might remain unknown.

These results are open, as the authors realize, to the criticism that the available plasmas must all be

mixtures of the A and B components, since it is virtually impossible to prepare completely purified substances, and that plasma from several species—dog, rabbit, human—were mixed. They are open to the greater criticism that the Quick hypothesis of two such separate substances is probably incorrect, and that results based on such hypothesis must be explained on other bases. The unitary nature of prothrombin seems in the stage of becoming well established.

THROMBOPLASTIC ACTIVITY OF THE URINE *L. M. Tocantins and J. N. Lindquist* From the Division of Hematology, Department of Medicine, Jefferson Medical College and Hospital, Philadelphia, Pa. *Proc Soc Exper Biol & Med* 65: 44-49, 1947

Experimental data are reported indicating that intact, protein-free and cell-free urine, as well as dialyzed urine, possess clot promoting activity when tested with normal and hemophilic blood, the behavior of the active agent resembling that of thromboplastin. Hemophilic urine frequently exerts as potent an effect as normal urine, occasionally, indeed, the former possesses greater clot accelerating properties than urine from normal individuals. Thus, an explanation is afforded for the frequent occurrence of clot formation in the renal pelvis of hemophiliacs with hematuria, the clotting time of whose blood, aspirated or shed from vessels elsewhere, may be markedly prolonged.

C P E

THE ACTIVE PRINCIPLE OF PLACENTAL TOXIN—THROMBOPLASTIN, ITS INACTIVATOR IN BLOOD—ANTITHROMBOPLASTIN *C. L. Schneider* From the Dept. of Physiology, Wayne University College of Medicine, Detroit, Michigan. *Am J Physiol* 149: 123-129, 1947

It has long been known that extracts of human placenta are toxic when injected into animals. The amount of toxic substance in a placenta can be determined quantitatively by a mouse-assay technic, as well as the amount of a corresponding inactivating material present in human blood. The nature of the placental toxin was tested by the author, and its chemical and physiological characteristics compared with those of thromboplastin. Placental toxin and thromboplastin behaved similarly in several respects. When serial dilutions of thromboplastin and of placental extract were made and tested, it was found that both showed similar curves of inactivation respectively by heat, by acidity, and by human serum. In addition, both behaved similarly in the ultracentrifuge. Heparin (antithromboplastin) was found to protect against the placental toxin in mice, both *in vitro* and *in vivo*.

Schneider concludes that the placenta is a potent source of thromboplastin, and that the toxic substance obtainable by extraction of placenta or of the progesterational uterus is thromboplastin. He speculates further whether this toxin might be related to the toxemias of pregnancy, and finds:

1. The anatomic lesions of eclampsia are consistent with thromboplastin poisoning. Mice given placental toxin showed clotting of blood in their small venules.
2. The concentration of anti-thromboplastin was found to be increased during pregnancy.
3. Pregnant animals are more sensitive to thromboplastin than are nonpregnant animals.
4. There are two reports in the literature suggesting that the anti-thromboplastic substance in the serum is decreased in eclampsia.

Therefore, the author speculates, cautious administration of heparin might be indicated in pre-eclampsia.

The concept is an interesting one. The nature of the toxemias of pregnancy is still controversial, however, the postulate that some sort of toxic substance is the cause has long been held. Termination of toxemia by termination of pregnancy supports the thesis that the 'toxin' arises from the products of conception. Whether thromboplastin could be the causative agent remains to be demonstrated. It is difficult to see how it could explain all the findings of eclampsia, such as persistent hypertension. The present highly preliminary report suggests, however, certain questions. Thromboplastin occurs in the normal as well as the eclamptic placenta, what is the factor which allows a normal pregnancy in the one individual, and toxemia in the other? Can eclampsia-like lesions be produced experimentally in animals by means of thromboplastin? Is the blood of eclamptic individuals high in thromboplastin content?

S E

DONNÉES RECENTES SUR LA COAGULATION (Recent statements on coagulation) *P. Frélicherq* (Actualités biochimiques M. Florkin) Desoer Edit. Liege, Belgique 1946

The chief interest of this important monograph resides in the fact that it is a synthesis of the Anglo-Saxon and Continental conceptions on coagulation. The first stage of the coagulation is the main object

of this study Frédéricq stresses the necessity of opposing the tissue extracts (lipoproteins) to the cephalin (lipoid). They differ on three main points: (1) Tissue extracts act in the same way on glass and paraffined glass, whereas lipoids are nonactive in the presence of paraffin, (2) Intravenous injection of lipoids is harmless, while tissue extracts provoke intravascular clotting, (3) Coagulation of hemophilic plasma is strongly accelerated by tissue extracts, but hardly affected by lipoids. According to Frédéricq, this discrepancy is explained by the necessity for the lipoids to react with a plasma factor. This factor quickly disappears in stored blood, and is named by Frédéricq 'Trypsin', it is a thermolabile euglobulin, probably identical to the plasma factors described by Widenbauer, Reichel, Leggenhager, Lozner and Taylor, Feissly, etc., and is lacking in hemophilia. It is through this trypsin that the calcium-platelet system, which is not in itself proteolytic, is able to activate the prothrombin. According to Frédéricq, the Quick's time does not only refer to the prothrombin level, but also to the trypsin concentration. To him, the A and B components described by Quick for the prothrombin, are the trypsin (A) and the prothrombin itself (B). The Russell venom, in opposition, is concerned only with prothrombin, being itself proteolytic. This thorough study includes 303 bibliographic references.

A CASE OF PURPURA FULMINANS WITH FIBRINOGENOPENIA IN ASSOCIATION WITH SCARLATINA H Døggve
From the Blegdamshospitalet, Copenhagen, Denmark *Acta Med Scand* 127 382-395, 1947

The author discusses the history of purpura fulminans first described by Henoch in 1887 and points out that one third to one half of the cases occur after scarlet fever. A number of cases, however, showed no preceding disease. In scarlet fever the purpura generally appears in the second to fourth week of the primary disease, which may be strikingly mild. Hematologic data are usually normal, except for secondary anemia after the bleedings. Blood cultures almost always are negative. The author found a prolonged coagulation time and this has also been noted by another observer.

The case was a boy of 3½ years. Scarlet fever was not severe. On the twenty-first day after the beginning of the disease large blood spots appeared after a hot bath. Both legs were swollen and later there was swelling and bluish discoloration of the lumbar region. A coagulation time of 14 minutes, with a small, loose clot, later increasing to 30 minutes was the most remarkable hematologic finding. The patient ran a high fever and the hematomata increased. He was treated with two large blood transfusions and vitamin K as the prothrombin time was increased. Determinations of fibrinogen were then performed and the very low value of 0.06 grams per cent was noted. Probably the fibrinogen content was still lower before the transfusions. After two further transfusions the condition improved in spite of several abscesses which formed in the hematomata. The antistreptolysin titer increased from 160 to 900. There was continued improvement and an examination nine months later was normal.

This is obviously an instance of the very rare condition, fibrinogenopenia. It should be noted that the patient was first regarded as suffering from hypoprothrombinemia as the Quick test was positive. The poor quality of the clot however led to the correct diagnosis.

Fibrinogenopenia has been noted in 2 cases of purpura fulminans. In one case following chicken pox the patient recovered after large transfusions. The blood remained fluid for two days and the plasma fibrinogen was 0.015. The other case died 24 hours after the bleeding was noted, and there was no previous malady.

Penicillin against the streptococcal infection and large blood transfusions combined with convalescent serum from scarlet fever patients is obviously the treatment of choice.

Another instance of purpura fulminans was lately published by S. Heindl, *Acta Paediatrica*, 34 147, 1947.

In this instance there was no previous malady noted in a 3 weeks old child which died in 46 hours from the onset of the disease. Hemolytic streptococci were cultured post mortem from the hematomata, the liver and the ascitic fluid. Penicillin and blood transfusions were not given, nor was plasma fibrinogen determined.

J W

PURPURA FULMINANS AND ITS RELATION TO SCARLATINA H Frödin From the Stockholm Hospital for Infectious Diseases, Stockholm, Sweden *Acta Paediatrica* 34 217-233, 1947

The case is that of a boy 5 years old, who, on the fifty-seventh day after scarlet fever developed typical erythema exudativum multiforme with slight temperature. On the sixty-third day ecchymoses spread over both legs, and small petechiae were noted on the trunk. Hematuria developed. Penicillin and blood

transfusions were given. There were maximally prolonged bleeding, coagulation and prothrombin times, but fibrinogen was not determined. Blood culture was negative. Exitus after three days of purpura. The very long coagulation time seems to indicate that a lack in fibrinogen may have been the cause of the bleeding and makes the importance of large blood transfusions obvious.

A survey of the cases with purpura from the Hospital for Infectious Diseases in Stockholm during the last 25 years showed no other instances of purpura fulminans.

J W

PURPURA NECROTICA. A POSSIBLE CLINICAL APPLICATION OF THE SHWARTZMAN PHENOMENON. J H Sheldon

From the Royal Hospital, Wolverhampton, and the Hallam Hospital, West Bromwich, England. Arch Dis Childhood 2: 7-13, 1947

The differential diagnosis of purpuric lesions is often very difficult, especially in children, and if the purpura cannot be readily explained as a symptom of one of the more commonly recognized diseases (leukemia, idiopathic thrombocytopenia, hemophilia) there is a tendency to list it as one of the heterogeneous group known as vascular purpura. From this wastebasket, from time to time, specific subtypes of vascular purpura are collected and reported as entities. Among such more or less definite disorders are pseudo-hemophilia, Schönlein-Henoch purpura, and purpura simplex. In the present report, Sheldon separates an additional small group of purpuric disease to which he gives the name purpura necrotica.

Three cases are described in girls aged 11 months, 3 years, and 5 years respectively. In each the history was essentially the same: there was a sudden onset of pains in the limbs, sometimes with swelling of the eyelids, hands, feet, knees, and ankles, then easy bruising and severe purpuric eruptions best described as hemorrhagic bullae. The notable feature of these purpurae was their geometric contours: they formed triangles, squares, and linear structures. After two weeks of acute illness, recovery began. During this stage, the lesions became stony hard, then the black overlying skin peeled off to leave healthy granulation tissue, and finally healing occurred by the slow granulation process over a period of from six weeks to two years. The large lesions left tremendous scars which resembled, because of their depth and extent, healed gunshot wounds. The children had no other residua. Little detailed laboratory study was possible. The platelets were normal in the 2 cases in which they were enumerated. Slight secondary anemia and leukocytosis were present. The bleeding and coagulation times were normal in one case. Cultures of the lesions gave no growth.

Two other similar cases were gathered from the literature by Sheldon, in one of whom splenectomy was followed by death because of sepsis. Sheldon speculates upon the nature of the disorder, and especially upon the curious configuration of the lesions. He notes that several of the angulated lesions occurred in areas of pressure: for example, one large buttock lesion corresponded to the pressure exerted by a pillow upon which the patient had sat for some time, and other smaller lesions were consistent with pressure from wrinkled bedclothes. He points out that, if somehow the area had become sensitized, subsequent prolonged pressure over a period of time might result in severe local tissue damage with accompanying hemorrhage (purpura). In the experimental Schwartzman phenomenon, an intradermal injection is used to sensitize a local area which becomes engorged and necrotic after a subsequent systemic (intravenous) injection. In the present disease, according to Sheldon, it is possible that the angioneurotic edema and periarticular swelling seen early in the course may sensitize the tissue cells which, upon pressure by bedclothes, chairs, etc., break down in geometric patterns with the resulting curious picture of purpura. This concept, of course, does not explain the fundamental nature of the disorder, which Sheldon believes is probably an allergic purpura, the subsequent peculiarities being the result of the Schwartzman like phenomena.

S E

CONGENITAL THROMBOCYTOPENIC PURPURA. J Talmadge and B Berman. From the Pediatric Service, St Louis City Hospital, St Louis, Missouri. J Pediat 30: 691-695, 1947

Thrombocytopenic purpura, developing in the neonatal period, is reported in three successive offspring of a mother with idiopathic thrombocytopenic purpura treated with complete relief by splenectomy three years prior to the first pregnancy. No observations are recorded pertaining to the course of her hemorrhagic diathesis following splenectomy, apart from prenatal examinations when she constantly exhibited

marked thrombopenia, prolongation of the bleeding time and, during the latter months of the first and third pregnancies, the recurrence of spontaneous bleeding. The three infants exhibited at birth a profound thrombocytopenia and associated manifestations of the disease, spontaneous recovery proceeding in each instance from the third to sixth week post partum and becoming complete within two months

C P E

THE PERIPHERAL VASCULAR SYSTEM AND ITS REACTIONS IN SCURVY. AN EXPERIMENTAL STUDY. R E Lee and N Z Lee. From the Department of Physiology, College of Physicians and Surgeons, Columbia University, New York. Am J Physiol 149 465-475, 1947

Microscopic observations were made under relatively physiologic conditions of the mesenteric capillary bed in normal and scorbutic guinea pigs. The size of the capillaries, the nature of the capillary wall, the status of capillary blood flow, the occurrence of petechiae, and the effects of trauma and of adrenalin were studied

Scurvy was found to be associated with certain definite abnormalities of the capillaries, especially a dilated peripheral vascular system and a slowing of blood flow. The small arterioles and the precapillary sphincters were found to be unresponsive to adrenalin. Atony and sluggish flow of the venules were marked. No petechiae were present in either the normal or the scorbutic animals, but slight traumata frequently produced petechiae in the guinea pigs with scurvy, but rarely in normals.

Scurvy, therefore, resulted in a decreased responsiveness of the contractile elements of the peripheral blood system, and in dilatation and engorgement of the small venules. The means by which the vascular hypotonia is produced is discussed by the authors, who speculate on the possible implication of the adrenal glands (it is known that the ascorbic acid content of the adrenal glands is low in scurvy, and that a reduction in ascorbic acid results in a depression of the activity of the adrenal cortex). The vascular atony, by allowing sluggishness of blood flow and therefore engorgement, may allow the vascular hemorrhages which are characteristic of scurvy.

NEWS AND VIEWS

The following has been received from the William Buchanan Blood Center

To the Editor

So that you will have some background of the Blood Bank Institute held in Dallas, November 17, 18, and 19, and the formation of the American Association of Blood Banks, I am giving you a few facts in which I thought you would be interested. I am attaching hereto a copy of a Blood Bank Survey* which I compiled from information contained in questionnaires sent to more than one hundred blood banks throughout the U S A in 1945. Being new in the blood bank field myself when I came to this blood center, I endeavored to procure information concerning the operation of other blood banks and was surprised to find that no one seemed to be in a position to furnish me with such information, therefore I set about trying to procure first a list of blood banks. This was indeed a tedious and drawnout task. After compiling a rather complete list, I then prepared a questionnaire which I submitted to these blood banks, as a result of which the attached survey was compiled, said survey being sent to those blood banks which had furnished me information. You will note that Question 37 asked, "Would you be interested in becoming a member of a National Association of Blood Banks designed to meet the needs and study problems of blood banks in general?" As a result of the interest indicated in reply to this question the Blood Bank Institute was planned and the resulting National Association formed.

At the Institute there were 71 cities, 27 states and 57 blood banks represented. Hawaii, Canada and Mexico also had representatives at the meeting. I am enclosing a copy of the program† as well as the constitution of the American Association of Blood Banks and copies of the five resolutions adopted by the Association, as well as a list of the officers. If you need any further information, please do not hesitate to call upon me. I personally appreciate your interest in this meeting and the resulting Association as it is very dear to my heart, and I am hopeful that much benefit will be derived by all blood banks participating from the Association formed.

Sincerely yours,
WM BUCHANAN BLOOD CENTER

Round Table Administrative Problems in Blood Banking, ' Dr Joseph M Hill, *Chairman*

To the Editor

I am sure you know by now that our Blood Bank Institute (held in Dallas, Texas, November 17-19, 1947) resulted in the formation of the American Association of Blood Banks. Although the original purpose of the Blood Bank Institute was for the presentation of methods of establishing and operating blood banks, and for the teaching of new technics for processing blood for transfusions, it soon became evident that those registering for the Institute were also interested in the formation of an association of blood banks.

The newly formed association decided that its membership would be limited to ethical, independently operating and policy making, nonprofit institutions, including those operated by approved hospitals, engaged in blood banking.

The stated purposes of this association are

- 1 To promote and foster the exchange of ideas and materials and the dissemination of information relating to Blood Banking and its technical methodology by education, publicity and research,
- 2 To foster and plan for cooperation in times of disaster,
- 3 To function as a clearing house on questions relating to the training of personnel common to such institutions,
- 4 To keep currently aware of and encourage high standards of service,
- 5 And to promote and foster and aid and abet the extension of similar services throughout the United States and its territories.

The resolutions adopted by the Association were definitely intended to put blood bank problems on a local level with the medical profession by way of the county societies acting in an advisory capacity. Through this approach each organized blood bank could serve the medical profession and the community on the basis of local conditions, demands and patient needs.

The capacity for meeting catastrophes by independent blood banks has been demonstrated in the recent past. During the Texas City disaster the Galveston and Dallas blood banks proved that immediate cooperation of a high order is possible on the part of the independent blood bank even though no previous plan had been formulated. During this disaster the Buchanan Blood Center became the collection and processing center and shipped the blood by air to the John Sealy Blood Bank, which then served as the giving center. In the meantime, the Harris Memorial Blood Bank of Fort Worth was standing by in case the blood demands exceeded our capacities. You might be interested to know that twelve hours from the time of the first explosion (four hours after we had been notified) our blood bank was collecting 100 pints of blood per hour for Galveston. In the future the Blood Bank Association hopes to make such cooperation nation-wide, and even more effective.

Sincerely yours,
Sol Haberman, Ph D

FIRST REPORT OF THE COMMITTEE FOR CLARIFICATION OF THE NOMENCLATURE OF CELLS AND DISEASES OF THE BLOOD AND BLOOD-FORMING ORGANS

To the Editor

A committee for clarification of the nomenclature of cells and diseases of the blood and blood-forming organs held its first meeting in Chicago at the Drake Hotel and Northwestern University Medical School October 25-26, 1947. The committee was sponsored by the American Society of Clinical Pathologists and the American Medical Association.

The function of the committee is to define areas where agreement can be reached, not to determine questions of fact requiring new experimental evidence for conclusive proof

The need for clarification and definition of terms is so urgent, not only for the sake of those now using them but particularly for the sake of the medical students and technicians of the future, that an earnest effort to find and secure general acceptance of a single term, where several with similar definitions are now in use, is thoroughly worth while

The choice of a preferred term, it was agreed, should be based not on historical priority or common usage, but the simplest, clearest and most descriptive term should be chosen. Eponyms and new terms should be avoided wherever possible, without sacrifice of clarity. A real effort should be made to attain consistency between related terms

All recommendations of the committee are to be tentative until they have been widely publicized and acted on by all interested groups. The committee will welcome any suggestions and criticisms. A committee should re-examine the terms every five or ten years. A full report on the Committee's deliberations will be published in a subsequent issue of the Journal

EDWIN E. OSGOOD, M.D.

THALASSEMIA, COOLEY'S ANEMIA OR MEDITERRANEAN ANEMIA?

To the Editor

Since Cooley, in 1925, separated the now well known syndrome as a new entity, various terms have been proposed for its description. Most of these terms, beginning with Cooley's own "Erythroblastic Anemia," are unfortunate misnomers. In 1936, Whipple and Bradford, apparently with more zeal and less deliberation, proposed the name "Thalassemia," which unfortunately is appearing with increased frequency in the literature, due more to the prominence of the authors, rather than to its medical or literary merits.

The Greek word "thalassa" means "sea," just "sea," not the "Great Sea" or even "The Sea." The Mediterranean Sea is called "Mesogeios Thalassa," "mesogeios" meaning "mediterranean," ("amidst the land"). If the Greeks usually meant the Mediterranean, whenever they mentioned the sea, it is just because the Mediterranean surrounds all Greek lands, just as the people of New York refer to the Atlantic whenever they mention the ocean, while the people of San Francisco mean the Pacific.

However the term "thalassemia" is unfortunate from another point of view. According to usage, the first component part of a composite word qualifies the second. Thus, glycemia means sugar in the blood, lipemia, fat in the blood (Vid cholesteremia, azotemia, etc). Likewise, hematuria (blood in the urine and not urine in the blood). Hence "thalassemia" should mean "sea in the blood," which, of course, is absurd. Even substituting the suffix "-anemia" instead of "(h)-emia," forming thus the word "thallasanemia," would not convey the intended meaning,

but according to grammatical and etymological rules, should mean "anemic sea," or at best "anemia caused by the sea" (Vid Thalassophobia fear of the sea), or, a condition where the sea is in the blood of the anemic person

I believe that the term 'Mediterranean Anemia,' good or bad, is more adequate, if we care to put geographic limitations to the syndrome, even though we no longer think that the condition has such strict geographic limitations. And, despite all objections to the use of authors' names in medical terminology, 'Cooley's Anemia' may be retained, since it is now precisely understood by all

SAVAS NITTIS, M D

Asst Clinical Professor of Medicine, New York Medical College

Dr Nittis has, I believe, a very good point. Although I have used the designations "target cell anemia" and "Mediterranean target-oval cell syndromes" in writing, I find in conversations that the relatively simple designation "Mediterranean anemia" seems to be increasing in usage. It is certainly indicative of the locale of inheritance of the great majority of cases and although it does not describe the type of anemia, it is far more descriptive than the eponymic "Cooley's Anemia." I, myself, would be inclined to drop the designation of target-oval cell syndromes for Mediterranean anemia. *Editor*

THE "COAGULATIONISTS" A NOTE ON THE FORTHCOMING MEETING

Following the wishes of "coagulationists" expressed at the Chicago meetings last year, we shall this year again plan a special section to bring together papers in this field at one of the sections of the Pathological Society where past experience has shown that we can have a most successful get-together. A luncheon will be held in conjunction with the Federated Societies at Atlantic City, between March 16-19

BOOK REVIEW

Heparin in the Treatment of Thrombosis, ed. 2 By J. ERIK JORPES Oxford University Press, London, England, 1946

It was in 1916, while Jay McLarn in Howell's laboratory was engaged in the purification of cephalin obtained from heart muscle, that he found a preparation which, instead of accelerating the coagulation of blood, greatly delayed it. From the first Howell felt that this newly discovered substance would find a suitable application in experimental physiology and possibly in the treatment of disorders of coagulation. A slow appreciation of the need for this type of therapy, and difficulties in the purification of the anticoagulant, delayed adequate fulfillment of this prophecy until 1935, when Best and a group of Toronto workers (Charles, Scott, Murray, Waters, Jaques) succeeded in purifying the substance and demonstrating its thrombosis-preventing properties, experimentally and clinically.

By 1939 enough facts had accumulated to lead Dr. Jorpes to publish a monograph on heparin. The present second edition of this monograph brings together additional facts developed in the past seven years. Chapters I, II and III are concerned with the chemical composition, mode of action and site of formation of heparin. The author's work has been chiefly concerned with these phases of the subject. In narrative style he takes the reader through the steps of chemical identification of the compound and the events which led to tracing the site of formation of heparin to the mast cells of Ehrlich (now designated as 'heparinocytes' by the author).

Chapter IV is devoted to a discussion of methods for the standardization of heparin. The author wisely states that the anticoagulant activity of heparin must be measured in biologic systems, since no physicochemical or color reaction will give reliable results. If, however, as stated, 'The quantitative determination of heparin in its natural milieu is almost an impossible task, how is one to explain the fairly consistent results in titrating heparin (with protamine) when this anticoagulant is added directly to the blood?' The fact that neither protamine nor toluidine blue, even in small amounts, can reduce the rate of coagulation of normal blood, must then indicate that heparin as such is not present in the blood, though it may be brought in from the tissues under certain pathologic conditions. This may also account for the fact that no figures are available, and none were found in this book, on the physiological concentrations of heparin in normal human blood. The propriety of referring to heparin as the physiological anticoagulant is, therefore, questionable.

The remaining three-fourths of the work deals with the clinical applications of heparin, including its use as an anticoagulant for chemical determinations and transfusions. Detailed instructions are given for the administration of the anticoagulant, with a discussion of diseases in which it can be of help. Specific case reports illustrate some of the conclusions. The text is abundantly supported with statistical data, collected principally in the Swedish Clinics. When one pauses to think that the author is a biochemist, it is surprising that the clinical sections are so well handled. Moreover, he manages to maintain a critical attitude, though his enthusiastic espousal of this form of treatment is obvious.

As said by Prof. Learmonth in the foreword, 'The monograph is complete: there is here assembled in a form readily available, an account of every aspect of a subject.' Even a section dealing with dicoumarol and its use in the prevention and treatment of thrombosis is included, presumably because this drug is being used more and more in combination with heparin. Clinicians, physiologists and biochemists may well turn to this book for clear, authoritative information on a drug and a method with increasingly wider applications.

CLINICAL SIGNIFICANCE OF CARDIAC AND RESPIRATORY ADJUSTMENTS IN CHRONIC ANEMIA

By HERRMAN L. BLUMGART, M D, AND MARK D. ALTSCHULE, M D

I INTRODUCTION

THE SUPPLY of oxygen to the tissues depends on the oxygen carrying capacity of the blood and the ability of the cardio-respiratory system to aerate and to transport the blood to each living cell of the body. The purpose of this communication is to review the status of the cardio-respiratory system and the related manifold compensatory mechanisms which provide a maximal supply of oxygen to the tissues in the presence of anemia. An understanding of these adjustments is necessarily based on knowledge of the changes in cardio-respiratory dynamics and on an appreciation of the nature of the clinical manifestations.

Most of the physiologic studies reviewed here have been published during the past twenty years. These two decades were most fruitful, for it was during this period that it became possible to study the same patients before and after effective therapy. This was the direct consequence of the discovery by Minot of the therapeutic effectiveness of liver, and the studies in iron therapy which were also carried out to an important extent in his laboratories.

II CHANGES IN CARDIOVASCULAR DYNAMICS

The Minute Volume Output of the Heart

Numerous investigations have shown that with anemia there is an increased cardiac minute volume output of the heart. The relation between the severity of anemia and the degree of increase of the minute volume output observed in different studies has not, however, been uniform. Similarly, the relation of the changes in minute volume output to other aspects of circulatory dynamics has also varied in different investigations. This is hardly surprising, when one considers the number of variable factors involved.

The method used to measure the minute volume output of the heart in man have been of necessity indirect, and have depended, until recently, on respiratory techniques. The complexity and technical variations of these methods have made quantitative comparison difficult and the number of measurements inevitably meager for statistical study. In many communications, the actual minute volume output values

From the Medical Service and Medical Research Laboratories, Beth Israel Hospital, and the Department of Medicine, Harvard Medical School, Boston, Massachusetts.

have been related directly to the hemoglobin concentration of the blood without regard for the fact that variations in cardiac minute volume output in normal people tend to be proportional to variations of the surface area and of the oxygen consumption. Anemias, moreover, are frequently related to, and indeed may be caused by, diseases which in themselves affect cardiac output because of fever or nutritional disturbances.

Plesch⁸⁶ in 1909 observed that the cardiac output increased when there was a decreased hemoglobin concentration of the blood. Utilizing the Fick principle, he found that the increase in cardiac output roughly paralleled the decrease in hemoglobin. Confirmatory results have been reported by other investigators^{15, 22, 37, 38, 10, 67, 75, 80, 92, 97, 100-103} who used a variety of methods, but Kininmonth's results⁶² are discordant. Several excellent studies in which measurements were made in the same subjects both in the anemic state and after improvement are of particular interest.^{10, 80, 92, 101, 103} On the basis of twenty-two observations in 8 individuals, Richards and Strauss⁹² concluded that there was a definite, though not entirely constant, tendency for the cardiac output to increase with decreasing hemoglobin concentrations, this general relationship as well as the variation disclosed in the individual instances applied to both the cardiac minute volume output and to the cardiac index, or the ratio between cardiac output and surface area. Results obtained by more accurate methods based on cardiac catheterization have become available recently. In a series of anemic patients studied by Sharpey-Schafer,⁹⁷ cardiac output was elevated 50 to 150 per cent over the normal average of 5.3 liters per minute, and generally was greatest at the lowest levels of hemoglobin concentration. Similar results have been reported by others utilizing the same technic.¹⁶

There has been no uniform agreement as to the level to which the hemoglobin concentration falls before the cardiac output is definitely increased. Dautrebande⁸⁸ observed an increase only when the hemoglobin fell below 50 per cent. Although others have expressed the opinion that a considerably lesser degree of anemia may cause a measurable rise in cardiac output,⁷⁵ no unequivocal rise in the cardiac output was observed in the studies by Brannon and his associates¹⁵ until the hemoglobin concentration was less than seven grams per cent.

Relation Between Cardiac Minute Volume Output, Metabolic Rate, and Coefficient of Oxygen Utilization

When the oxygen carrying capacity of the blood is diminished in a patient with anemia, two mechanisms are available to maintain an adequate supply of oxygen to the tissues, these mechanisms may act singly or together. The first mechanism which may compensate for deficient concentration of hemoglobin consists of an increased delivery of blood to the tissues consequent to increased cardiac output. If the concentration of hemoglobin were 50 per cent of normal and the cardiac minute volume output and blood flow were doubled, the amount of oxygen withdrawn from each cubic centimeter of blood in the capillaries might be one-half the normal, but the total amount of oxygen given off to the tissues would be unchanged. Despite the low arterial blood oxygen content, the venous blood oxygen

concentration would remain normal. Since the venous blood oxygen tension reflects that of the tissues it is clear that tissue anoxia would be prevented. Sole reliance on this mechanism would require the heart to expend a greatly excessive amount of energy in order to prevent tissue anoxia, and the circulatory reserve would be encroached upon to a marked degree.

The minute volume output of the heart, other factors being equal, is also related to the total oxygen consumption of the body. If the total oxygen consumption of the body were markedly increased in the presence of anemia, part of the increased minute volume output of the heart would be attributable to this factor. Most observers, however, have found normal values while others have observed small increases in some instances, this will be discussed below. Thus, the increased output observed in anemia can be ascribed only slightly, if at all, to increased total oxygen consumption of the body.

The second mechanism available for maintenance of an adequate supply of oxygen to the tissues consists of more nearly complete abstraction of oxygen from the blood as it passes through the capillaries. Normally, 100 cc of arterial blood contains approximately 21 cc of oxygen. Under normal basal conditions, only about 5.5 cc, i.e., approximately 30 per cent, are removed from the blood as it passes through the capillaries. The remaining 15.5 cc may be regarded as reserve oxygen which can be called upon during exercise or other unusual states to prevent asphyxia of the tissues. The anemic patient, to the extent to which he relies on the mechanism of more complete oxygen abstraction, diminishes his reserve oxygen and sacrifices this factor of safety; the degree of sacrifice would depend upon the severity of the anemia. Moreover, the gradient between the oxygen tensions of capillary blood and that of the cells of the tissues must be less under these circumstances.

The data available in the literature clearly demonstrate that the burden of anemia on the cardiovascular system is distributed, part being assumed by an increase in the cardiac output per minute and a part by the increased percentage, i.e., coefficient of utilization, of oxygen by the tissues. The actual amount of oxygen abstracted from the blood as it courses through the capillaries of an anemic patient is less than normal, but the ratio between the amount abstracted and the subnormal amount initially present in the arterial blood is actually greater and is reflected in the increased percentage of oxygen utilization uniformly observed in patients with severe anemia. It should be noted that normally an A-V oxygen difference of 5.5 grams per 100 cc of blood signifies an A-V difference of approximately 30 per cent of the available oxygen. If there were no increase in cardiac output in severe anemias with less than 30 per cent hemoglobin, the amount of oxygen which could be delivered to the tissues, even with 100 per cent abstraction of oxygen, would be less than the normal oxygen supply. In the most severe degrees of anemias, 80 to 90 per cent of available oxygen is removed, were it not for the increased percentile abstraction, higher values of cardiac output than those actually observed would be required to maintain adequate minute oxygen supply. Thus, increased cardiac output and increased percentile removal of available oxygen are two adjustments which serve to maintain adequate oxygen supply.

The above considerations bear on the interesting question of what should be considered 'the normal cardiac output,' a concept which has important theoretic as well as practical clinical implications. The normal cardiac output must be considered the cardiac output which is found in healthy subjects at rest and free of discomfort or emotional tension, at medium ambient temperatures and with normal rates of body oxygen consumption. The normal cardiac output varies considerably but is proportional to the surface area, the cardiac index, i. e., ratio of cardiac output per minute to surface area, being relatively constant in all normal subjects. The cardiac index is proportional to metabolic rate. In the presence of congestive failure due solely to cardiac disease there is a decreased cardiac index in relation to bodily requirements for oxygen which remain unchanged or are even increased.² When, however, anemia supervenes in the presence of congestive failure the index is not as low as one would anticipate on the basis of congestive failure alone, the cardiac output being somewhat increased rather than diminished in relation to total body oxygen consumption of normal subjects. For example, in the presence of severe anemia with arterial oxygen content of five volumes per cent the cardiac index is approximately seven.¹⁵ This elevation of the cardiac index to more than twice the normal of healthy subjects is the increase whereby the requirements of the body for blood and oxygen are met. An elevation less than this constitutes circulatory insufficiency even though the output at such times may be larger than that of normal subjects. When the cardiac index is below that indicated for the degree of anemia, even though markedly above the so-called normal of healthy individuals, the circulation may be insufficient in relation to the increased demands of anemia, congestive failure may ensue.

In the presence of lowered oxygen consumption in anemic patients, the expected increased cardiac output may not always be present. Thus Starr et al.¹⁰⁰ state "The two cases of anemia did not show the increased cardiac output which we expected. Both of them appear to have reduced their basal metabolism to a point where a normal cardiac output will carry the necessary oxygen. In one of these patients, starvation may well have been the cause of this decrease. This method of compensating for anemia is not that usually described." Similarly in patients with anemia of myxedema, the cardiac output may be low but adequate for the lowered metabolic requirements, congestive failure does not develop.

This general principle applies equally to other conditions which demand an increased output, such as thyrotoxicosis, arterio-venous aneurisms, pregnancy, febrile states, and, indeed, exercise.

The Velocity of Blood Flow

The relation between volume flow and velocity flow of liquids of fixed viscosity through tubes of known diameter is a simple one and is expressed by the equation, $V = A/\pi r^2$ where V is velocity flow expressed in seconds, A is the volume flow per second and r is the radius of the tube. If other factors remain equal, an increase in volume flow will be accompanied by a proportional increase in the velocity of blood flow. With the somewhat decreased viscosity of blood in anemia, an additional factor tending to increase the velocity of blood flow is operative. The extent to which

pulmonary blood flow is accelerated in the presence of anemia was studied by Blumgart, Gargill, and Gilligan¹¹ using the radioactive method. Thirty-two complete series of measurements were made in 29 subjects with pernicious anemia and with anemia secondary to a variety of diseases. The results showed that, while there were considerable variations, the velocity of blood flow through the lungs in these patients generally tended to increase in proportion to the degree of anemia. A linear relationship between the increased cardiac output and accelerated velocity of blood flow was observed by Stewart et al.¹⁰³, the greater the cardiac output, the shorter the circulation time. The increase in velocity observed by the latter investigators was of somewhat greater magnitude than that reported by Tarr, Oppenheimer and Sager,¹⁰⁶ but similar to those results recorded by Blumgart et al. With increased speed of blood flow through the lungs, accelerated pulse rates were observed. Other studies of circulation time in patients with anemia have been reported by many authors^{4, 9, 10, 13, 33, 36, 38, 56, 60, 63, 66, 70, 71, 74, 84, 106, 112}, all are in accord with the above.

Regulation of Peripheral Blood Flow

Calculation of the average peripheral resistance throughout the body in patients with anemia indicates that a definite decrease is present. However, the state of the small blood vessels is not uniform everywhere. Thus plethysmographic measurements of blood flow in the arms¹ and studies based on estimation of local arterio-venous blood oxygen or carbon dioxide difference in the arms^{3, 25, 30, 43, 51, 76, 79, 86, 92} show accelerated flow while blood flow in the hands is diminished^{1, 104} in anemic patients. Direct observations of the capillaries in the skin of the fingernail fold show marked vasoconstriction^{30, 50} and flow is slow.³⁰ The occurrence of increased peripheral flow everywhere except in the hands is identical with the pattern of flow seen in simple anoxia such as is produced in normal subjects breathing air deficient in oxygen.

Measurements of antecubital and mixed venous blood oxygen content yield very low values.^{3, 15, 25, 51, 76, 79, 86} In spite of the fact that the tissues are given enough oxygen for their basal requirements, as shown by the fact that total oxygen consumption is not lowered in anemia, the low tissue oxygen tensions which exist result in a diminution of the margin of safety. The occurrence of intermittent claudication of the calves in patients with anemia has been emphasized by Pickering and Wayne.⁸⁵ In accord with the concept that the tissues are anoxic is the fact that blood lactic acid values are often elevated in patients with anemia⁵⁸ and the ability of the body to metabolize intravenously injected lactate is impaired.^{21, 45} After exercise the oxygen debt is greatly increased in anemic patients⁸¹ presumably as a consequence of the accumulation of excessively large amounts of lactic acid.

Visceral Blood Flow

¹ *Kidneys* The observations of Bradley and Bradley¹⁴ on renal blood flow in anemia are of interest in that they afford data indicating the presence of selective changes in vasomotor activity. The renal blood flow is greatly diminished in patients with chronic anemia, evidently as a consequence of localized vasocon-

striction. Calculations of the filtration fraction suggest that afferent vasoconstriction is somewhat more marked than that in the efferent arterioles of the glomeruli. Although flow of blood through the kidneys is reduced by a third or a half, the amount of *plasma* presented for filtration to the glomeruli per unit of time as a rule is almost normal because of the low hematocrit values which occur in anemia. Accordingly nitrogen retention is uncommon. On the other hand the observed reduction in blood flow may be related to salt retention observed by Strauss and Fox¹⁰⁵ in patients with anemia (see below). Evidence of impaired tubular function, presumably consequent to anoxia, is also presented by the Bradleys.¹⁴

2. *Bram* Himwich and Fazekas¹⁸ recorded observations on arterial and jugular venous blood gas concentrations in one anemic patient, which indicate that the flow of blood through the brain is abnormally rapid in anemia, the venous blood oxygen concentration, however, and presumably the tissue oxygen tension in the brain, is very low. These authors ascribed the development of mental symptoms in their patient to anoxia.

The Metabolic Rate in Anemia

A review of the available data indicates there are no striking deviations from the normal total oxygen consumption of the body as a consequence of anemia per se. The problem is complicated by the fact that the metabolism of the body may be influenced considerably by the disease which causes the anemia.²⁶ In pernicious anemia, Boothby and Sandiford¹² observed that approximately 10 per cent of their patients had a metabolic rate above plus 20 per cent. Similarly, an average increase in basal metabolic rate of plus 20 per cent was observed in the 5 patients with pernicious anemia studied by Stewart et al.,¹⁰⁷ a decrease to an average of plus 6 per cent occurring during remission induced by treatment. In patients with iron deficiency anemia, the metabolic rate is increased less frequently and is often normal or below normal. In the 18 patients studied by Brannon et al.¹⁵ the average metabolic rate in patients with less than 7 grams per cent of hemoglobin was plus 13, as compared with plus 5 per cent in patients with hemoglobin between 7 and 13 grams, and minus 7 per cent in their normal subjects. In general, the rise in oxygen consumption by the body in anemia is at most small or frequently absent, even when present, the increase in cardiac output and velocity of blood flow can be attributed only in small part to this rise in oxygen consumption.

Blood Volume

Neither the carbon monoxide method nor the dye methods measure absolute blood volume in normal subjects, experience with pathologic subjects tends to confirm and extend this conclusion. Either method may on occasion give the larger value and it is not possible to assert that either one consistently measures absolute blood volume, both methods apparently tend to exaggerate the true blood volume. The dye method also generally gives excessive values for the plasma volume.⁶³ It is fairly clear, however, that most methods give fairly reliable qualitative but not quantitative measures of the relative plasma volume. Observations by various investigators of the blood volume in anemia reveal that the blood volume is some-

what reduced^{11, 30, 34, 35, 38, 97}, the most thorough studies are those of Gibson et al.^{34, 35} The mean plasma volume per kilogram of body weight is usually within the limits of normal, however, so that the diminution is a reflection of reduction in total circulating red cell mass.

III CHANGES IN RESPIRATION

Alterations in Ventilation

The respiratory minute volume is often increased in anemia, even beyond what might be expected in the presence of occasional elevations of the metabolic rate.^{8, 16, 57, 64, 66} Some authors have found no striking change in certain instances.^{23, 92} Increases in rate and in depth of respiration participate in the elevated respiratory volume. Although these findings suggest the effects of simple anoxia, it is clear that other influences operate in patients with anemia.

All authors who have measured the vital capacity in patients with anemia have found lowered values in many of their subjects.^{11, 57, 64, 87} More detailed studies, involving estimation of the subdivisions of the vital capacity, i.e., the reserve and complementary air volumes, show these to be lowered likewise.^{64, 87} The residual air is increased somewhat.^{64, 87} These deviations from the normal are similar to those observed in pulmonary congestion or edema and denote a loss of elasticity and expandability. Changes of this type favor the occurrence of exertional dyspnea.

Blood Gases and Their Relation to Dyspnea

Studies of the blood gases in anemia are of importance in understanding the dyspnea which may occur in this disorder. Arterial anoxia obviously must exist when the hemoglobin level is reduced. Although some of the earlier observers reported also that low arterial blood oxygen saturation was common,^{55, 86} most workers agree that the saturation is normal in patients at rest.^{43, 49, 51, 79} Accordingly it is apparent that the degree of pulmonary congestion and/or edema present in severe anemia is not sufficient to interfere with maximal oxygenation of the blood. On the other hand, during exertion, arterial blood oxygen saturation falls markedly,⁴⁹ indicating inefficiency of the respiratory mechanisms under conditions of strain. The reduced oxygen saturation of the arterial blood conceivably might be due to some qualitative alteration of the hemoglobin in anemia, however, the oxygen dissociation curve of blood from anemic patients is normal at all pH levels found in man.^{25, 91, 99}

As pointed out above, the tissue oxygen tensions or at least the gradient between blood and tissues must be greatly lowered. This phenomenon exists in the brain, as was shown by Himwich and Fazekas⁴⁸ and provides an additional mechanism for hyperventilation.

Another group of factors important in consideration of the respiratory dynamics of anemia is related to peculiarities of carbon dioxide transport in that disorder. Joffe and Poulton⁵⁹ showed by means of experiments *in vitro* that erythrocytes are important in carrying carbon dioxide, and Smith, Means and Woodwell⁹⁴ further showed that red cells *in vivo* may actually carry most of the carbon dioxide given off by the tissues. Accordingly it is clear that a fall in erythrocyte count must im-

pair transport of that gas. There is an apparent contradiction in this concept in the fact that the whole blood of anemic patients has a carbon dioxide combining power which is in or even above the upper normal range^{7 19, 23, 51 51, 79 98}, the carbon dioxide combining power is estimated using whole blood, and since each unit of the blood in anemic patients contains relatively more plasma and fewer cells than normal, the great carrying capacity for carbon dioxide of plasma as compared to cells, which exists normally, results in the small increase observed in the whole blood. However the role of plasma in the transport of carbon dioxide given off by the tissues may be minor, that of the erythrocytes more important, this is evidenced by the fact that plasma and red cells do not participate equally in the changes to be described.^{25 12} The loss in anemia of much of the buffering action normally provided by hemoglobin in the red cells and the resultant flattening of the carbon dioxide dissociation curve^{7 19 25 44 51 78 82 109} is highly significant: a given amount of carbon dioxide entering the blood causes much greater increases in carbon dioxide tension and hydrogen ion concentration than occurs when the blood hemoglobin concentration is normal. Hyperventilation, which makes the arterial blood somewhat alkalotic in patients with anemia,^{7 19 23 25 92} enables the blood as it traverses the tissues to accommodate this tendency toward acidosis, the arterio-venous difference for pH is thereby increased^{3 7 43 92} but the pH of the venous blood,^{7 29} and presumably of the tissues, remains normal.

It has been noted that some types of chronic anemia are associated with less exertional dyspnea than others of the same degree and chronicity but of different types. Clearly, factors other than those discussed above must be important in this regard. In addition to hemoglobin, the red cells contain other respiratory enzymes, including carbonic anhydrase. The latter catalyzes the reaction $\text{HCO}_3 \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O}$ in either direction, depending on concentrations of the substrate materials. Earlier work with this enzyme tended to minimize its importance in the etiology of dyspnea because, according to the methods used in the past, there is such an enormous excess of this enzyme that it was considered impossible that a deficiency could ever exist, in the adult at least. There are, however, certain errors in these older methods which led to the finding of falsely high values in normal blood.⁷² By the use of a newer method it has been found that the amount of activity of the enzyme in normal blood is so small that a decrease, because of disease, would lead to serious impairment of the rate of absorption of carbon dioxide by the blood in passing through the tissues and the release of carbon dioxide from the blood in passing through the lungs.⁷² Several workers^{52 67 68, 72} have studied the relation between carbonic anhydrase activity and hemoglobin content of the blood in normal subjects and patients with anemia. It has been found that anemias due to blood loss, malnutrition, chronic infection, uremia or leukemia are associated with a proportional reduction in blood carbonic anhydrase activity which is parallel to the decrease in hemoglobin level.⁷² Patients with any of these types of anemias, therefore, not only have decreased oxygen carrying capacity but also may have a deficiency in ability to take up carbon dioxide from the tissues and to release it in the lungs. Therefore, not only is anoxia responsible for their hyperventilation and dyspnea on exertion but carbon dioxide accumulation in the tissues is probably also a factor.

On the other hand, patients with Addisonian pernicious anemia may have no deficiency in blood carbonic anhydrase activity^{67, 68, 72} and consequently suffer from no impairment of carbon dioxide transport and excretion from lack of the enzyme itself. The reason for this difference between macrocytic and micro- or normocytic anemias is not clear.

In summary, the following factors, many of which are closely interrelated, are operative in the production of dyspnea in anemic patients: the increased respiratory minute volume, the decreased vital capacity and its subdivisions, abnormalities in carbon dioxide transport and dissociation, reduced arterial oxygen capacity and the decreased blood oxygen saturation during effort, the frequently observed elevated blood lactic acid values.

IV CLINICAL MANIFESTATIONS OF CHRONIC ANEMIA

Cardiovascular and Respiratory Symptoms and Signs in Anemia

With the exception of active rheumatic infection, bacterial endocarditis, periarteritis nodosa, disseminated lupus erythematosus, and advanced organic tricuspid disease, organic cardiovascular disease does not cause anemia. Various cardiovascular symptoms and signs occur, however, in the presence of anemia and have attracted the interest of many observers for more than a century. Practically all investigators have concerned themselves with isolated aspects of the problem. Excellent comprehensive clinical studies of the cardiovascular system in anemia were, however, presented by Ellis and Faulkner in 1939²⁸ and by Wintrobe¹¹³ and Hunter in 1946,⁵⁴ the last named also providing an extensive bibliography, which will therefore not be repeated here. Wintrobe¹¹³ also includes an excellent digest of some of the physiologic adjustments of the cardiovascular system in anemia.

1. *Symptoms* Lassitude, anorexia, dizziness, palpitation and breathlessness on exertion generally are found in patients with moderate or severe degrees of anemia. In even the severer grades of anemia, however, breathlessness is rarely present at rest, and orthopnea and paroxysmal dyspnea are absent. Palpitation likewise is generally experienced only with exertion and implies an increase in the rate as well as in the force of the cardiac impulse. Anginal pain may occur particularly on effort.

2. *Physical signs* Pallor of the skin and mucous membranes, changes in the tongue and finger nails, and slight degrees of edema, particularly over the sacrum and lower legs, are characteristic of the anemic state. Increased vigor of arterial pulsation with a widened pulse pressure was frequently observed by Sharpey-Schafer⁹⁷ who also described capillary pulsation in the finger tips. In the severer grades of anemia, "pistol shot" sound over the larger arteries, a positive Duroziez sign, and systolic murmurs on auscultation may be manifest. The possibility that these evidences of vasodilatation may be related not to anemia but to associated fever or beriberi must be borne in mind.

3. *Cardiac enlargement* Bamberger in 1857⁶ and Friedreich in 1861³² commented on the pathologic findings of fatty infiltration and degeneration, together with dilatation and increased weight of the heart in patients with anemia. Ball¹ was the first to demonstrate an increase in heart size by x-ray measurements with return to

normal after recovery, this finding has been confirmed by many observers^{28, 41, 51, 89, 107} Twelve of the 34 patients studied by Hunter⁵¹ showed definite cardiac enlargement during anemia, with return to normal size in all but 3 following appropriate treatment. In some patients with slight or doubtful degrees of enlargement a decrease in size following disappearance of the anemia was noted. The reduction in size was always generalized, but in addition any straightening of the left border which had been initially present was replaced by a normal concavity. Cardiac enlargement tends to occur more frequently in patients with particularly low hemoglobin levels and, according to Hunter,⁵¹ there is a decrease in enlargement when the hemoglobin percentage rises to the levels of 60 to 95 per cent, variation being observed in different subjects. Regression in cardiac size usually occurred early, often within two or three weeks of the beginning of treatment and at hemoglobin levels still substantially below normal.

Cardiac hypertrophy, however, is also frequently present.^{17, 18, 28, 30, 54, 89, 90} The available data seemingly support the opinion of Porter^{90, 91} that primary cardiac dilatation is a physiologic adjustment resulting from the increased cardiac output in the presence of a supply of anemic blood through the coronary arteries to the myocardium. If the anemia is rectified early, dilatation disappears and heart size returns to normal. If, however, prolonged dilatation continues with stretching and injury to the myocardial fibers, cardiac hypertrophy inevitably develops.⁹⁴ The degree of cardiac hypertrophy is usually not marked, but an instance is cited by Cabot^{17, 18} in which the heart weighed 710 grams in the absence of arterial hypertension and coronary arteriosclerosis, the heart of a patient observed by Porter weighed 630 grams.⁸⁹

In general, it may be said that both dilatation and consequent hypertrophy undoubtedly occur in patients with anemia, but that there is no direct relation between the incidence or degree of enlargement and the severity of the anemia. With the return of the hemoglobin levels toward normal, cardiac size usually returns to within normal limits, although occasional instances of persistent slight enlargement may be witnessed. In addition to dilatation and hypertrophy, the anemic heart muscle undergoes a form of fatty degeneration characterized by yellow streaking ("tigering") clearly visible on the endocardial surface.

4 *Heart sounds* A loud and booming first sound is frequently heard in patients with anemia, but no direct relation to the hemoglobin level or the duration of the anemia is apparent.^{54, 89, 90} The prolongation and accentuation of the apical first sound may closely resemble the characteristic first sound in mitral stenosis. The aortic and pulmonic sounds are usually not altered, but in some patients an additional third heart sound is heard at the apex. This latter finding has been corroborated by phonocardiography, and must be considered abnormal since the patients were over 30 years of age.⁵⁴ Both the booming first sound and the presence of the third sound were associated with a moderate tachycardia, and disappeared when the pulse rate slowed.

5 *Cardiac murmurs* That a blowing systolic murmur commonly is heard at the apex or over the mitral area in anemic patients is generally appreciated. Occasionally, however, such murmurs are heard over the aortic and pulmonic areas, and at

times they may be rough or even rumbling and may be accompanied by diastolic murmurs. Attention should be called to the fact that in rare instances a blowing diastolic murmur may also be heard along the left border of the sternum characteristic of aortic insufficiency. Most observers have encountered these diastolic murmurs only rarely. While Goldstein and Boas³⁹ reported an incidence of 10 per cent of these murmurs in 39 cases of anemia, these diastolic murmurs occurred only in association with severe degrees of anemia. The blowing apical systolic murmurs tend to be louder, longer, and less affected by posture and by respiration than the same systolic murmurs encountered in healthy young persons. They are usually not transmitted to the axilla. When, however, they have a rough, rumbling quality and are associated with a booming first sound and the slight or moderate cardiac enlargement seen in the presence of moderate or severe anemia, the differentiation from structural mitral disease may offer difficulty and, indeed, the distinction may be impossible. In such unusual instances, decision may have to be deferred until further observations are made when the anemia is alleviated.¹¹³

It is of interest, that of the 34 patients studied by Hunter⁵⁴ while they were moderately or severely anemic and again after treatment, 30 showed cardiac murmurs, always systolic in time except in one case which showed an early diastolic murmur and another a pre-systolic murmur. Six murmurs were described as faint, 16 as moderate, and 9 as rough. In 29 cases, murmurs were heard at the apex, in 21 at the pulmonary area, and in 6 in the aortic area. Twenty had murmurs at more than one site, i.e., mitral and pulmonary in 14, mitral, pulmonary and aortic in 6. An apical murmur alone was present in 9 cases and a pulmonary murmur in 1. Aortic murmurs were always accompanied by both pulmonary and mitral murmurs. The louder murmurs were heard in two and often three areas, and the softer in single areas, generally the mitral. When multiple murmurs were present, they were loudest at the apex, then in the pulmonary area, and least loud in the aortic area. The murmurs were usually diminished when the patients were in the erect position, especially when the intensity had lessened after treatment. In 9 patients the murmurs, though not accompanied by thrills, were loud enough to raise a suspicion of valvular disease, although their distribution made such a diagnosis unlikely. The two diastolic murmurs, one late or pre-systolic at the apex, and the other early in the fourth left interspace near the sternum, led to diagnoses of mitral stenosis and aortic incompetence respectively, until their disappearance with treatment indicated their hemic origin. The incidence of murmurs was not directly related to the severity of the anemia, for they were often conspicuous when it was slight and absent when it was considerable. The duration of the anemia seemed more important.⁵⁴ ¹¹³ The patients described by Schwartz and Legere⁹⁶ illustrate in striking fashion the difficulties which sometimes arise in the differentiation of cardiovascular changes due to anemia from those consequent to serious organic heart disease.

The wide-spread belief that cardiac enlargement is the cause of hemic murmurs was not confirmed by Hunter,⁵⁴ since their association was inconstant, and noticeable murmurs were heard when the heart was normal in size and occasionally absent when there was enlargement. It is probable that acceleration of blood flow is an important cause of the murmurs noted, however, the decreased viscosity of the

blood which accompanies anemia favors the development of eddies and therefore of murmurs, as Wiggers¹¹⁰ pointed out

As mentioned above, cardiac enlargement usually diminishes rapidly while the murmurs tend to persist over a longer period of time. Treatment usually effects a lessening in the intensity of the murmur and most murmurs disappear or become negligible when the blood findings return to normal. In a few instances, however, such murmurs may persist for several months before disappearing.

6 *Tachycardia* Moderate increase in the cardiac rate is nearly always present with moderate or severe anemia, the rate rising to 90 to 100. The relation between the rise in pulse rate and the degree of anemia is variable. In studies on the velocity of blood flow through the lungs, Blumgart et al.¹¹ observed that the pulse rate was more closely related to changes in the velocity of the pulmonary circulation than to variations in the degree of anemia. This result is hardly surprising since the cardiac rate and the velocity of blood flow are both characteristics of the general circulatory adjustment and as such are more closely related physiologically to each other than to change in the oxygen carrying capacity of the blood.

7 *Arterial blood pressure* In the presence of moderate or severe anemia, a lowered blood pressure is commonly observed with a subsequent rise as recovery from the anemia occurs.^{15 85 101} Although the 5 patients studied by Stewart et al.¹⁰¹ exhibited a rise in arterial pressures amounting in 3 of their patients to as much as 50 to 80 millimeters and 30 to 46 millimeters of mercury in the systolic and diastolic pressures respectively, other workers found lesser changes. Similar, though not as striking or uniform findings, were reported by Brannon et al.,¹⁶ while Bradley and Bradley¹⁴ found no consistent change. This tendency for the blood pressure to rise with recovery from anemia occasionally counterbalances the decreased work of the heart which also occurs at this time due to lessened volume output and velocity of blood flow during recovery, it may result in the work of the heart being approximately the same in some patients during anemia as after recovery.¹⁰³ The rise in arterial pressure which may develop is a reflection of the increase in total peripheral resistance which occurs when the need for visceral vasodilatation is no longer present as the hemoglobin level approaches normal. The somewhat widened pulse pressure sometimes seen in anemia with narrowing of the span after recovery is in accord with this concept.

8 *Venous pressure* The right auricular pressure in patients studied by Sharpey-Schafer⁹² was usually a high normal. A slight elevation was noted in one of 5 patients by Stewart et al.¹⁰³ while no significant alterations were noted in the other 4 patients. No elevation was found by other authors.^{38 106} Sharpey-Schafer⁹⁷ believes that the increased output is achieved mainly by the raised venous pressure, a concept which requires further verification.

9 *Electrocardiographic changes* Numerous studies of the electrocardiogram in chronic anemia indicate that, while abnormalities occur in approximately a quarter or more of such patients, they are minor in degree and are not specific for anemia. Prolongation of the QT interval,¹⁰⁷ flattening or inversion of T in one or more leads,²⁷ low amplitude,^{108, 114} transitory prolongation of the P-R interval,⁸⁵ depression of the ST segment²⁸ have been noted. A return to normal of the electrocardio-

gram was sometimes observed after treatment, although this did not always occur even when there was no reason to suspect other forms of heart disease. In 2 of the 25 patients studied electrocardiographically by Hunter,⁵⁴ gross abnormalities were apparent, but in spite of successful treatment of the anemia, the electrocardiogram was unchanged on re-examination a year later, both patients were in the fifth decade and the changes may have been consequent to coronary arteriosclerosis or other lesions.

The possibility of vitamin B deficiency, digitalis administration and, in some patients, the effect of the disease responsible for the anemia, are difficult to exclude in some of the reported cases although these factors were evidently ruled out in the studies by Ellis and Faulkner²⁸ and Hunter.⁵⁴

The electrocardiographic changes frequently apparent in chronic anemia are similar to those observed during acute anoxia. That anoxia is an important factor is further supported by the frequently transitory character of the changes in moderate or severe anemia. In some patients, the electrocardiographic changes may represent the summation of anoxia, coexistent coronary arteriosclerosis, and fatty changes in the myocardium.

It is not surprising that the effects of anoxia are prone to occur in the heart during chronic anemia, for even under normal conditions the abstraction of oxygen from the blood as it flows through the heart is relatively great. Thus, mixed venous blood in the right chambers contains approximately 15 volumes per cent of oxygen and, as stated above, this amount of oxygen represents a reserve factor. On the other hand blood from the coronary sinus obtained in observations in man by catheterization techniques contains only approximately two volumes per cent. The abnormal reduction of this reserve factor in the heart, the lowering of blood pressure commonly observed in anemia, and the increased work of the heart attendant to the increased output predispose to anoxia.

Angina Factors and Severe Anemia

Herrick^{46, 47} drew attention to patients with severe anemia who developed angina pectoris, and who experienced relief when the anemia improved, this was confirmed subsequently by many other investigators.^{16, 20, 27, 28, 54, 61, 85, 88, 111, 114} It is to be expected that in any large series of patients with anemia an occasional instance of coincidental angina pectoris might be encountered. The fact, however, that angina pectoris first appears in some patients with the development of severe anemia and is alleviated by appropriate treatment of the anemia bespeaks an etiologic interrelationship. Such patients are encountered only occasionally and are almost always in the age group in which coronary arteriosclerosis is more common. Cabot¹⁷ and Elliot,²⁷ however, have both reported cases in which no evidence of coronary artery disease was found postmortem. In most patients of this type, however, it is probable that the heart is damaged to so slight an extent that it is able to maintain an adequate blood flow provided that the oxygen carrying capacity of the blood is normal. In the presence of anemia, however, the increased amount of work necessary to compensate for this condition cannot be accomplished readily, particularly since the blood supply to the heart is affected in common with

that of the rest of the body. Furthermore, the normally large utilization of available oxygen by the heart predisposes to the induction of ischemic muscle pain in severe anemia.

Congestive Failure in Anemia

The necessity for the maintenance of the cardiac output and cardiac work at an abnormally high level for long periods of time, and the delivery to the myocardium of blood deficient in oxygen together favor the occurrence of myocardial insufficiency. Other factors favoring it are present when the patient with severe anemia also is in the age group in which coronary artery disease and hypertension occur, as is common in pernicious anemia and anemia due to carcinoma. Nephritic anemia usually is also complicated by the presence of hypertension. The coexistence of organic cardiovascular disease, added strain upon the heart due to anemia and anoxia of the myocardium are especially prone to result in congestive heart failure. When this syndrome develops the circulatory dynamics change.⁹⁷ The right auricular and venous pressures become elevated, the lungs become more congested, and the cardiac output, although often still elevated in comparison to the normal, becomes lowered relative to the values which ordinarily obtain with a given degree of anemia. The arm-to-tongue circulation time in such instances represents the resultant of two opposing factors, i.e., a tendency toward slowing due to congestive failure on one hand and toward acceleration due to anemia on the other, it often lies in or close to the normal range as a consequence. Patients in whom myocardial insufficiency develops as a consequence of anemia have aggravation of their antecedent exertional dyspnea, as is to be expected from the superimposition of the additional mechanisms favoring dyspnea which occur in chronic congestive failure.⁹ Such patients are likely to respond poorly to digitalis unless the anemia is corrected. On the other hand, since congestive heart failure develops in patients with anemia when the heart is less seriously damaged than in those in whom cardiac decompensation is referable to heart disease alone, the ultimate outlook, assuming adequate therapy of the anemia, is better in the former than in the latter.

Dyspnea is not necessarily an indication of congestive failure. Dyspnea may be consequent to anemia per se and as such may be the resultant of the action of a number of factors, each of which has been discussed above. These include the effect of low arterial blood oxygen concentrations on the carotid body, the effect of low tissue oxygen tensions directly on the brain, the effect of low oxygen tension in exaggerating lactic acidosis on effort, and the effects of impaired carbon dioxide transport, the latter requires arterial alkalosis to prevent tissue acidosis. These mechanisms all favor hyperventilation and thereby contribute to dyspnea. In addition the changes in the subdivisions of the lung volume indicative of some degree of congestion and/or edema point to a pulmonary factor in the genesis of the exertional dyspnea seen in severe anemia. Still another factor favoring exertional dyspnea is the high cardiac output at rest which reduces the cardiac reserve available for exercise. None of these mechanisms is altered by the administration of digitalis or other forms of therapy directed at cardiac decompensation, they all respond favorably when the anemia is treated successfully.

As in the case of dyspnea, there is a tendency toward edema formation inherent in anemia even in the absence of congestive failure. Older clinicians are aware of this phenomenon and younger physicians still see it occasionally in spite of the earlier diagnosis and more adequate therapy of anemia which obtain today. Peters and Eisenman⁸³ in a thorough analysis of the relation of the level of the plasma protein to edema in various diseases noted that patients with anemia developed edema at levels of plasma protein well above those seen in other diseases associated with edema, with the exception of congestive heart failure, these authors were unable to explain this phenomenon. The change in capillary permeability noted as occurring in animal preparations under anoxic conditions⁶⁹⁻⁹⁵ may have some bearing on the problem. On the other hand, it is to be noted that Strauss and Fox,¹⁰⁵ in a study entitled "Anemia and Water Retention," showed that retarded excretion of sodium, varying in degree with the severity of anemia, was present. A tendency of this sort toward salt retention suggests the involvement of some renal mechanism, as pointed out by Bradley and Bradley¹⁴ in their discussion of the occurrence of markedly reduced renal flow in anemia. Many years ago Rowntree and Fitz⁸⁴ caused salt retention in animals by inducing renal vascular stasis. It is clear that edema may occur in anemia even in the absence of congestive heart failure. The edema of anemia, like the dyspnea of anemia disappears when the anemia is cured. When exertional dyspnea, edema and the commonly occurring hepatomegaly of severe anemia occur together, the diagnosis of myocardial insufficiency suggests itself. However, the absence of venous engorgement and more especially of orthopnea contradict that diagnosis. Absence of cyanosis is not helpful, for as Lundsgaard and Van Slyke⁷⁷ showed, it is impossible for cyanosis to develop under any circumstances in patients with less than five grams per cent of hemoglobin.

V. SUMMARY

The cardiac and respiratory adjustments in chronic anemia and their clinical manifestations have been reviewed. When the oxygen carrying capacity of the blood is diminished, an adequate supply of oxygen to the tissues is maintained by an increased cardiac output, an increased velocity of blood flow, and a relatively more complete abstraction of the oxygen from the blood as it passes through the capillaries. With the increased blood flow, the average peripheral resistance is decreased but the state of the small blood vessels is not uniform everywhere, the blood flow in the hands and kidneys, for instance, may be reduced, while that of other parts of the body is increased. The total oxygen consumption of the body in anemia is not strikingly altered. The blood volume generally is slightly reduced but the plasma volume is normal.

The deviations from the normal values vary from patient to patient, but generally are definite when the hemoglobin values are less than 50 per cent and are greatest at the lowest levels of hemoglobin concentration.

The close interrelationship between the cardiovascular and respiratory systems is exemplified by the coincident changes in the respiratory system in anemia. The rate and depth of respiration often are increased together with a lowering in the vital capacity and its subdivisions, the reserve and complemental air volumes. The resid-

ual air is somewhat increased. These deviations from the normal are similar to those observed in pulmonary congestion or edema and denote a loss of elasticity and expansibility favoring the occurrence of exertional dyspnea. The arterial blood saturation is usually normal at rest but, during exertion, a significant lowering becomes apparent.

The importance of hemoglobin in the transport of carbon dioxide is reviewed, the decreased availability of hemoglobin as a buffer in carbon dioxide transport in anemia is compensated by the increased ventilation of the blood in the lungs, rendering the arterial blood somewhat alkalotic. The red cells also play an important role in regard to the respiratory enzyme, carbonic anhydrase. In the anemias due to blood loss, malnutrition, chronic infection, uremia, or leukemia, the blood carbonic anhydrase activity is parallel to the decrease in hemoglobin level leading to a deficiency not only of oxygen carrying capacity but also a decreased ability to absorb carbon dioxide from the tissues and to release it in the lungs. The following factors, many of which are closely interrelated, are operative in the production of dyspnea in anemic patients: the increased respiratory minute volume, the decreased vital capacity and its subdivisions, the abnormalities in carbon dioxide transport and dissociation, the reduced arterial oxygen capacity and the decreased blood oxygen saturation during effort, and the frequently observed elevated blood lactic acid values.

The symptoms and signs exhibited by anemic patients, including palpitation and breathlessness on exertion, tachycardia, cardiac dilatation and hypertrophy, are described. In addition to an apical systolic murmur, other systolic and diastolic murmurs are occasionally heard. The arterial blood pressure is frequently lowered in anemia, the venous pressure is generally within the limits of normal. Electrocardiographic abnormalities occur in approximately one-quarter of anemic patients but are minor and not specific in character.

The occurrence of angina pectoris, congestive failure, and intermittent claudication in some patients with the development of anemia, and disappearance of these conditions as the anemia is alleviated, is discussed with particular reference to the underlying physiologic mechanisms.

IRREVERSIBLE TOXIC "INCLUSION BODY" ANEMIA

A RARELY RECOGNIZED SYNDROME, CLINICAL AND EXPERIMENTAL STUDIES

By M H FERTMAN, M D , AND CHARLES A DOAN, M D

A PATHOLOGIC entity, apparently rarely recognized, and unreported in recent American and British hematologic clinical literature, is a form of refractory anemia characterized by peculiar "inclusion bodies" in the circulating red blood cells. First reported by Heinz in 1890¹ and noted by Ehrlich in 1892^{2a} in experimental poisonings with pyrodine, dinitrobenzol and other related compounds, "Heinz Inner-Kopern" may be readily identified in plain dried blood films, and are described in wet preparations, stained with brilliant cresyl blue or Nile blue sulphate, as deep blue, eccentrically placed spheres of varying size and number within the erythrocytes.³ They are readily distinguished from Howell-Jolly bodies, siderocytosis, and classic reticulocytosis by their characteristic appearance, distribution and staining reactions.⁴ They have gone undetected in most routine clinical laboratories probably because in the usual Wright-Giemsa stained and mounted blood films prepared for microscopic study they are difficult to demonstrate.

Our own attention has been currently focused upon this phenomenon by the discovery of its occurrence in the blood of an elderly physician with an unexplained refractory anemia, which terminated fatally despite the use of all available therapeutic measures.²⁰

CLINICAL OBSERVATIONS

Dr M, #4410193, a 71 year old white male physician, was admitted to the Hematology Service, University Hospital with complaints of weakness, anorexia and nausea of four weeks duration. Attacks of angina pectoris of increasing severity and frequency had been noted for approximately four years. Eight weeks prior to this admission the patient first began to experience some dyspnea, orthopnea and moderate pedal edema.

Examination revealed an obese elderly male showing marked pallor of the skin and mucous membranes with a slight icteric pigmentation. His tongue showed no atrophic changes, and lymphadenopathy was nowhere apparent. The chest was increased in the antero-posterior diameter and fine scattered rales were heard in both lung bases. The heart was moderately enlarged to the left on percussion. A soft blowing apical systolic murmur was present. The blood pressure was within normal limits. The liver edge was palpable 6 cm below the right costal angle, the spleen was not enlarged. Rectal examination revealed a diffusely enlarged firm prostate with no tenderness and no nodules. There was slight pitting edema of the ankles. Vibratory and position sense and deep tendon reflexes were physiologic.

The patient was temperature-free throughout his entire course in the hospital except for one transitory, mild thermal post-transfusion reaction.

Electrocardiograms demonstrated sinus tachycardia and low voltage with evidence of myocardial damage. X-ray examination of the chest showed moderate enlargement of the heart with diffuse densities in both lung fields, suggestive of some cardiac congestion. Roentgenographic examination of the stomach and lower gastrointestinal tract showed no evidence of organic pathology. X-ray plates of the skull, long bones, and bony pelvis were entirely normal.

From the Division of Medical Research, Department of Medicine, Ohio State University, Columbus, Ohio

The admission blood study revealed 2,331,000 red cells per cu mm, 5.6 grams of hemoglobin per 100 cc, and 16,100 white cells with 83 per cent mature motile neutrophils and 13 per cent normal, small lymphocytes. Serial urinalyses and kidney function tests were consistently normal. The sedimentation rate, blood phosphorus and phosphatase, and blood urea nitrogen were within normal limits. The test for Bence-Jones protein in urine and plasma were repeatedly negative. The hippuric acid excretion was only 1.88 Gm, prothrombin time 58.8 per cent, and blood proteins 4.68 mg with 2.83 mg albumin and 1.96 mg globulin. Gastric analysis revealed a normal amount of free hydrochloric acid, and stool examinations showed no occult blood.

During his fifty-nine days of observation in the hospital, the patient was given transfusions of whole blood, and washed, resuspended red blood cells, totaling 6 liters. His red cell count ranged between 1,810,000 and 3,980,000 per cu mm. Because of the macrocytic anemia with a megaloblastic bone marrow, he was given a therapeutic trial of a concentrated form of liver extract, reticulogen, 20 units daily for seven days. This was later repeated for a ten day period. Ferrous gluconate, 5 grains three times daily was administered for fifteen days in an effort to correct the hypochromia. The patient was digitalized and received aminophyllin for his cardiac status. Other supportive treatment, included high vitamin I complex supplement.

The reticulocyte count, which was 14.8 per cent at the time liver extract was first instituted, rose to a peak of 22.8 per cent after seven days, but was not followed by any significant increase in the total circulating red blood cells. Irrespective of therapy, the reticulocytes varied between 3 per cent and 15 per cent throughout the clinical course of the anemia.

On the twenty-third hospital day the mature red blood cells, stained with brilliant cresyl blue, were first observed to contain atypical inclusions, distinguishable from the regular reticulum. As many as 13 per cent of the erythrocytes contained these bodies. Inclusion bodies were noted from then on consistently in all daily preparations, in numbers varying from 1 to 16 per cent. How long these inclusions may have been present in the patient's circulating red cells prior to their detection is a matter of conjecture.

The patient was resurveyed with reference to a possible toxic etiology for his refractory inclusion body anemia. Attention was focused on the 500 $\frac{1}{4}$ grain erythrol tetranitrate tablets taken orally over the preceding year for his angina pectoris. Except for the rare use of nitroglycerine in cardiac crises no other drug had been taken. There was no history of food idiosyncrasies or other allergic sensitivity. The patient, a physician, stated emphatically that he had never been seriously ill or anemic in a long, healthy life until the present illness.

The patient was discharged at his own request on the fifty-ninth hospital day. At this time his peripheral blood showed 3,160,000 red cells per cu mm, with 0.6 per cent reticulocytes, 7.1 grams of hemoglobin and 16.2 per cent "inclusion body" erythrocytes. His white count had fallen to 3100 per cu mm, with 44 per cent neutrophils, 8 per cent eosinophils and 48 per cent normal lymphocytes. His platelet count was always adequate.

The anginal attacks continued with frequency and severity despite bed rest, digitalis and aminophyllin. Pallor, weakness and physical debility were progressive. The red blood cells continued to show marked macrocytic hypochromia, polychromatophilia, anisocytosis, poikilocytosis, and the presence of inclusion bodies. Fatal termination occurred one month after discharge from the hospital. Post mortem examination was refused.

CYTOLOGIC STUDIES OF THE PERIPHERAL BLOOD AND BONE MARROW

The peripheral blood showed extreme, bizarre, poikilocytosis and anisocytosis with large individual macrocytes and hypochromia. The reticulocytes were not unusual in appearance, as many as 14.8 per cent being found in the peripheral blood prior to liver therapy. No antianemic hematopoietic liver, iron, vitamins B and C, had any significant effect either on erythropoiesis or the hypochromia. Platelets occurred singly and in large clumps, and, occasional individual thrombocytes showed some qualitative changes, which included anisocytosis with sparse granulations (giant platelets). No pathognomonic alterations in the white blood cells were observed.

The bone marrow on repeated examinations appeared, grossly and microscopically, to be markedly hyperplastic. The erythroid elements were chiefly responsible for the cellular hyperplasia with a "left shift" to early erythroblasts and megakaryoblasts. There was also the hypochromia of iron deficiency. The myeloid elements showed a moderate "left shift," with more than the usual number of qualitatively normal myelocytes but no myeloblasts. There was an increase in small, normal young megakaryocytes. No foreign tumor cell invasion was seen. There were scattered phagocytic clasmacocytes. "Inclusion bodies" were observed rarely in the immature erythroid elements in our specimens of bone marrow.

On examination of the patient's blood with brilliant cresyl blue, there were found, in addition to the classic reticulocytes, certain inclusion-containing mature red cells. With this stain, the inclusions appeared as blue green globules of irregular shape, varying in size from barely perceptible dots to spheres almost 2 micra in diameter. They occurred sometimes singly, sometimes in great numbers, within the cell. They were most often concentrated at or near the cell membrane, and on occasion were seen in various stages of extrusion from the cell. They were found to be lysis-stable and resistant.

The inclusions could be seen in unstained living blood films as refractile yellow tinted bodies. In dark field examination they appeared highly refractile, globular and irregular, similar in general appearance and distribution to the inclusions seen in bright field. They were observed best in wet-mount preparations with brilliant cresyl blue stain, they were less clearly seen in fixed brilliant cresyl blue stained smears. Janus green with neutral red stain in supravital preparations readily revealed these "bodies." The inclusions were not apparent in fixed preparations stained with Wright or Wright-Giemsa dyes or with the Prussian blue iron technique.

The staining properties and morphology of these particular "inclusion bodies" distinguish them from Howell-Jolly bodies and siderocyte inclusions.⁵ Howell-Jolly bodies are readily stained in Wright and Giemsa fixed preparations and appear to be dark reddish blue dots. The siderocytes are characteristically identified with the Prussian blue reaction, which leaves a heavy deep blue iron precipitate within the red blood cell.

EXPERIMENTAL OBSERVATIONS

Following the discovery of "inclusion bodies" in the patient's erythrocytes, it was determined that erythrol tetranitrate was the only drug which had been taken for many months prior to and coincident with the development of the anemia, and to which the patient may have developed an idiosyncrasy.

Since this peculiar anemia persisted and continued to progress even several weeks after the presumed toxic agent was discontinued, some permanent irreversible damage must have been suffered by the erythropoietic tissues. Experimental procedures were therefore undertaken in an attempt to further identify the etiologic agent and establish the mechanism involved in this fatal anemia.

EXPERIMENT I EFFECT OF THE PATIENT'S PLASMA UPON NORMAL RED CELLS IN VITRO

Preliminary in vitro studies were conducted to determine whether there were any toxic substances present in the fresh whole plasma of the patient which would

affect normal human red blood cells. Venous blood was obtained from a normal subject whose blood-grouping and Rh type were the same as the patient's. These normal cells were separated and resuspended in the plasma obtained from the patient and kept in a refrigerator at 10 C. Daily examination with brilliant cresyl blue over a five day period failed to reveal the development of any "inclusion bodies" in the borrowed red blood cells.

Animal experimentation was then invoked, utilizing two fundamental approaches (1) transfer of laked blood and fresh plasma was made by infusion from the patient into rabbits, (2) both rabbits and cats were subjected to erythrol tetranitrate and allied compounds and the red blood cells studied for "inclusion bodies."

EXPERIMENT 2 EFFECT OF THE PATIENT'S PLASMA AND LAKED RED CELLS UPON THE RABBIT

Since the patient's red blood cells contained the abnormal "inclusion bodies," it was felt that a toxic factor might be found either in the patient's plasma or in his red cells.

"Inclusion bodies" did not appear in the erythrocytes of the rabbits which received intravenous injections either of plasma or of laked red blood cells from the patient. R 1A and R 2A each received one 10 cc injection of plasma and the blood was followed for four days. R 1 and R 2 received two injections of plasma (5 and 30 cc and 10 and 20 cc, respectively) on consecutive days and died within thirty to forty-five minutes after the second dose. R 3 and R 4 received three intravenous injections of laked blood (5, 10 and 5 cc, and 1 cc, 15 cc, and 5 cc respectively). R 4 died immediately following its third injection. No significant postmortem changes were noted in the spleen, bone marrow or other organs of the three rabbits which died.

EXPERIMENT 3 EFFECT OF SODIUM NITRATE AND ERYTHROL TETRANITRATE UPON ERYTHROPOIESIS IN THE RABBIT

Two rabbits (R 1A, R 4A) were then given massive doses of sodium nitrate every day subcutaneously. Necrosis at the site of injection necessitated substitution of the oral route via the stomach tube on the fifth day. In R 4A the dose was doubled from 100 to 200 mg /Kg on the fifth day and death occurred on the seventh. In R 1A the dose was increased from 500 to 1000 mg /Kg on the fifth day and to 2000 mg /Kg on the tenth. Death occurred on the eleventh day.

R 3 and R 2A received 50 to 300 mg /Kg doses of erythrol tetranitrate via stomach tube daily over a period of more than two weeks. R 3 was followed for three days after completion of a sixteen day course of the drug, while R 2 died on the fifteenth day.

Daily examination of the blood of these rabbits receiving either sodium nitrate or erythrol tetranitrate even in massive doses revealed no "inclusion bodies." No significant postmortem changes were observed in the hematopoietic organs in the three rabbits which died.

EXPERIMENT 4 EFFECT OF ERYTHROL TETRANITRATE UPON THE MONKEY

A *Macacus rhesus* monkey received three 180 mg /Kg doses of erythrol tetranitrate by stomach tube on the second, fourth and tenth days of observation. During daily observations for twenty-three days, a mild anemia was precipitated, without the development of "inclusion bodies," from which there was prompt recovery with cessation of the drug.

EXPERIMENT 5 EFFECT OF SODIUM NITRATE AND ERYTHROL TETRANITRATE UPON THE CAT

More suggestive results were obtained in experiments with cats. "Inclusion bodies" appeared within twenty-four to seventy-two hours in the red blood cells of all cats receiving either sodium nitrate or erythrol tetranitrate.

C 1 received a single subcutaneous injection of 1000 mg /Kg of sodium nitrate and C 2 injections of 500 mg /Kg on two consecutive days. In both, 'inclusion bodies' up to 9 and 10 per cent appeared within forty-eight hours after the initial dose and then gradually declined as the drug was eliminated.

Three cats (C 9, C 3, C 1) received oral doses of powdered erythrol tetranitrate, which was thoroughly mixed with raw meat. C 9 was given a single dose of 250 mg /Kg and showed at seventy-two hours 21 per cent of the circulating erythrocytes with typical 'inclusion bodies,' and at ninety-six hours 28 per cent, with a fall of 2,000,000 in red cells during this period. During the ensuing fifteen days the "inclusion body" erythrocytes gradually declined to zero per cent with a recovery in the red cells. In C 3, 200 mg /Kg of erythrol tetranitrate was administered on the fifth, sixth, eleventh and twenty-seventh days of observation, and 300 mg /Kg on the fifteenth and seventeenth days. A rare red cell containing 'inclusion bodies,' 1 per cent, was observed within twenty-four hours of the original dose. A peak of 15 per cent was attained after the last dose, associated with a drop of 1,000,000 in the total circulating red blood cells.

In C 1, weighing 2.8 Kg, erythrol tetranitrate was administered beginning nine days after one dose of 1000 mg /Kg of sodium nitrate. The 'inclusion bodies' had risen to 10 per cent within forty-eight hours of the sodium nitrate dosage and had gradually fallen again to 2 per cent by the time the first dose of erythrol tetranitrate (150 mg /Kg) was administered. The next day, another 150 mg /Kg of erythrol tetranitrate was given, followed by doses of 75 mg /Kg on the 3, 4, 5, 6, 11 and 12 days of observation. The 'inclusion bodies' rose to 26 per cent within the first seventy-two hours of the erythrol tetranitrate administration and varied from 11 to 28 per cent through the thirteenth day. The hemoglobin decreased from 13.3 to 11.2 Gm during the period. With discontinuance of the drug on the twelfth day, the 'inclusion bodies' declined to 5 per cent by the sixteenth day.

In the cats receiving sodium nitrate or erythrol tetranitrate, the concentration of 'inclusion bodies' did not vary directly with the dosage of the drug under the conditions of the experiment. With the cessation of the drug, the number of 'inclusion bodies' was noted to decrease promptly and to disappear entirely eventually. A decrease of between one and two million in the red cell count was

1

2

3

4

observed to occur in all cats from the time the first nitrate was administered. In C 9 recovery in the red cell count was soon evident with cessation of the drug.

EXPERIMENT 6 EFFECT OF MANNITOL HEXANITRATE ON CAT BLOOD

Less spectacular results were observed in two cats (C 6, C 10) fed mannitol hexanitrate, pulverized in meat. Despite relatively large doses of the drug (165 to 330 mg/Kg) only small percentages of "inclusion bodies" (1 to 6 per cent) were observed in C 10, and the red cell count showed no significant change.

An *old* cat (C 6), with an occasional "inclusion body" erythrocyte (0.5 per cent) even prior to nitrate administration, developed a maximum of 12 per cent of these after nine successive doses of mannitol hexanitrate (80 to 160 mg/Kg), the loss in circulating red cells totaling 4,000,000, hemoglobin 3 Gm over a thirty-four day period of observation. The rare occurrence of "inclusion bodies" in the red cells of older animals has been reported elsewhere in the literature.⁵

EXPERIMENT 7 EFFECT OF SULFANILAMIDE UPON CAT RED CELLS

Sulfanilamide was only questionably effective in the production of "inclusion bodies" under the conditions of this experiment.

In C 2, which had shown up to 9 per cent "inclusion bodies" with two 500 mg/Kg doses of sodium nitrate, the highest concentration of "inclusion bodies" observed after ten daily 400 mg/Kg (oral) doses of sulfanilamide was 4 per cent. Results were negative in an *old* cat, C 7, which showed no significant increase in "inclusion bodies" over a 5 per cent concentration demonstrable prior to sulfa drug administration, nine successive doses of sulfanilamide (800 to 1600 mg/Kg per dose). The red cell count and hemoglobin showed no consistent trend during the period of observation in either cat.

STAINING PROPERTIES OF THE "INCLUSION BODIES" IN CATS

The staining properties of the "inclusion bodies" observed in the erythrocytes in cats appeared to be similar to those in our patient. The "inclusion bodies" were seen readily in unstained preparations and in supravital preparations stained with brilliant cresyl blue, methylene blue and Janus green with neutral red (fig. 7). They were also seen, but less readily, in fixed preparations with brilliant cresyl blue. They were not apparent in preparations stained with Wright, Wright-Giemsa or with the Prussian blue reaction.

Certain differences were noted in the cellular reaction in the cats as contrasted with the patient. In the animal studies only a minor degree of poikilocytosis and aniso-

Figs. 1, 2. Brilliant cresyl blue supravital staining of the erythrocytes in patient's blood. Inclusion bodies as seen in bright field under oil immersion.

Figs. 3, 4, 5. Similar preparations of the peripheral blood from the patient as seen under dark field oil immersion conditions. Note highly refractile inclusion bodies. Figure 4 shows a separated inclusion body indicating the integrity of these Heinz inner körpers apart from the erythrocytes. Figure 5 identifies the peripheral location of these bodies at the cell surface.

Fig. 6. A bright field illustration of inclusion bodies from the patient's blood. Compare and contrast with similar bodies appearing in the blood of Cat #1 following erythroltetranitrate oral medication, FIGURE 7

cytosis was noted, whereas in the human blood, these changes were extreme. Perhaps this reflects the more profound hematologic disintegration in the patient, due to the much longer period of exposure to the drug. It was also observed that the "inclusion bodies" in cat blood tended to remain globular while "inclusion bodies" in the patient's blood were more bizarre in shape (figs 6-7). In addition the "inclusion bodies" observed in the cats under conditions of the experiment occurred in fewer numbers within each red cell than those observed in the patient.

The "inclusion bodies," both in the patient and in cats, were noted in various phases of extrusion from the red blood cell (figs 4,5,7). They were found within the cell, close to the periphery, producing a bulge in the red cell membrane and also lying free outside the red cell. "Inclusion bodies" in both human and cat blood were found to be lysis-resistant.

A specimen of cat blood, demonstrated to contain "inclusion bodies," was taken and selectively centrifuged to obtain a highly concentrated specimen of these "bodies." Spectroscopic examination of this specimen revealed no hematorporphyrin. This evidence, while suggestive, is not conclusive.

Bone marrow examinations were made in cat #1 after erythrol tetranitrate in massive amounts. Unlike the bone marrow of the patient, who had received the drug in small doses over a long period of time, the erythroid elements showed no maturation arrest and appeared normal except for the occurrence of small punctiform perinuclear inclusions in a few normoblasts.

DISCUSSION

Peculiar "inclusion bodies" were observed in the red blood cells of a 71 year old male physician who exhibited a severe anemia, which did not respond to either intensive iron or liver therapy nor to a high protein, high vitamin diet. Although folic acid as such⁶ was not available for treatment, large amounts of vitamin B₁₂ complex were given. There was no clinical evidence of any specific nutritional deficiency and there was no response to liver. The "inclusion bodies" were noted in the unstained preparation and were stained readily with supravital wet-mount technic, using brilliant cresyl blue and other reticulocyte stains. They appeared as blue green irregular globules, occurring singly and in numbers, within the mature red cells, and taking a position at the periphery. They were also seen in various stages of extrusion from the red cells and were noted to be hemolysis-resistant. The "inclusion bodies" were distinguished from Howell-Jolly bodies and from siderocyte inclusions. These various staining and morphologic characteristics were found to conform with those of the "Heinz Inner-Korpern" described in the German literature^{1-4,7} as occurring in "toxic" anemias in man and in animals.^{1-4,7-17}

The suspected etiologic agent, erythrol tetranitrate, which the patient had taken for angina pectoris over a period of one year, was administered to cats in massive doses. Lysis-resistant "inclusion bodies," with staining characteristics similar to those found in the patient's blood, were induced. A tendency toward anemia, reversible under the conditions of the experiment, with cessation of the drug, was observed. "Inclusion bodies" were noted to a lesser extent with sodium nitrate and mannitol hexanitrate. Only minimal concentrations of "inclusion-bodies" were

produced with large doses of sulfanilamide. We can confirm the report of German investigators⁸ that old animals show these "inclusion bodies" in a small proportion of circulating erythrocytes in the absence of any known external toxic agent.

Although erythrol tetranitrate and sodium nitrate were given in large repeated doses to rabbits, "inclusion bodies" were at no time observed. In a monkey receiving erythrol tetranitrate, a mild reversible anemia developed without demonstrable "inclusion bodies."

Cessation of drug administration to cats brought about a gradual disappearance of the "inclusion bodies" from the blood stream. Whether a longer course of drug administration would have produced an irreversible "inclusion body" anemia in the cat, such as that observed in our patient, remains unanswered.

The observance of a progressive, refractory, "inclusion body" anemia in an elderly patient, persisting even after four months' omission of the suspected toxic drug, would suggest the precipitation of an irreversible toxic alteration in the erythrocyte maturation process.

Various theories have been proposed to explain the formation, nature and significance of these "inclusion bodies." Freifeld⁸ suggests a genetic relationship between the so-called "Randkorperchen" (corpora marginalia) and these "Inner-Korpern" of Heinz and Ehrlich, the result of an enterogenous autointoxicant. These "inclusion bodies" were originally regarded as "dead toxic protoplasm,"^{1, 2} reflecting methemoglobin or sulph-methemoglobin poisoning.⁹ The more recent interpretation of these "Inner-Korpern," as denatured, cell-membrane proteins^{1, 10} has received support from Jung's observations⁷ with the electron microscope, which place these "inclusion bodies" definitely in the outer layer of the cell. Frank H J Figge, Associate Professor of Anatomy, University of Maryland, has studied the experimental production of Heinz-body erythrocytes.¹⁸ "When certain sulfonamides were dissolved in water administered to mice, large numbers of refractile bodies appeared in the erythrocytes. These bodies were insoluble in distilled water or 3 to 5 per cent acetic acid and made leucocyte counts difficult. They were similar to erythrocyte inclusions described originally by Heinz. Other investigators concur in this identification. It was found that a 0.3 per cent sulfanilamide solution given as drinking water induced Heinz bodies in at least 90 per cent of all erythrocytes within four to six days, while sodium sulfathiazole did not. The tendency of various sulfonamides to produce Heinz bodies appeared to parallel the tendency to induce hemolytic anemia. Further studies on the physical and chemical properties revealed that these bodies are globules of either denatured hemoglobin or cathemoglobin. Erythrocytes extrude these bodies as they form so that large numbers of Heinz bodies accumulate in the plasma as the erythrocytes become hypochromic. Heinz bodies are most easily observed in unstained, unmounted blood smears and disappear when examined in oil, balsam, or other mounting media. These globules of hem-containing protein, denatured within the cell by drugs, have been studied in detail because such a reaction is of interest both from the standpoint of cancer research and the mode of action of sulfonamide drugs. Dr. Figge in a recent personal communication¹⁹ further states: 'I still do not know the exact mechanism which is responsible for the production of these bodies. They can be produced in

small numbers by such diverse agents as cobalt, paraminobenzoic acid and acetanilide. I suspect that they are probably formed as a result of therapy with numerous other compounds but go undetected because blood is usually prepared for examination with some mounting medium. As you have probably noticed, these bodies are much more easily observed in plain dried blood films examined under the high dry objective."

The conception of 'Heinz Inner-Korpern' as nuclear fragments has not been confirmed, though Figge states "this protein, which is denatured, resembles in some respects a nucleoprotein."

Schilling, who noted 'all transitions' between typical Howell-Jolly bodies and the 'Inner-Korpern' following splenectomy,⁹ rejected this simple explanation.¹¹ The appearance of "inclusion bodies" in the peripheral blood of various normal animals following splenectomy^{3, 8, 9, 11} and of humans with splenic hypoplasia, subsequently demonstrated,¹ bears out the hypothesis of Heinz¹ and of Schilling⁹ that the normal spleen filters out the senile and damaged erythrocytes, which may contain these 'inclusion bodies.' This is further corroborated by the observation of 'inclusion bodies' (Giemsa stained Tupper preparation) as partly extra-cellular and partly extruding from the red cells in the human spleen.³ It is suggested that in the absence of a normally functioning spleen the inclusion-containing red cells may appear in the peripheral blood. The administration of a specific toxic agent further increases their numbers.³

Should it be considered, then, that minimal "inclusion body" formation may occur, in association with subclinical endogenous toxins, in otherwise normal individuals, but in numbers so small that they are ordinarily withdrawn by a physiologically functioning spleen? This concept might explain the more frequent observation of small numbers of inclusion-containing erythrocytes in the blood stream of senile animals,⁶ animals in whom the catabolic processes predominate and splenic efficiency perhaps may have diminished. In addition, there may be other states, such as dietary deficiencies, inherent specific susceptibilities and certain disease processes, which perhaps may predispose to 'inclusion body' anemia. One may also inquire as to whether the development of "inclusion bodies" may precede red blood cell destruction at some phase in anemic states other than those of "toxic" etiology. It has been shown that in poisoning with nitrates and their derivatives the extent of 'inclusion body' development parallels closely the destruction of the red blood cells.⁴

The known 'toxic' agents which may result in an "inclusion body" anemia in man and in animals are, in general, methemoglobin producing drugs, such as nitrobenzol,^{2, 11} aniline,^{8, 9} nitroglycerine,⁴ dinitroglycol,⁴ ethyl nitrate,^{4, 12} sodium nitrate,¹² nitrobenzol and toluol derivatives.^{8, 13} Even in the absence of a known "toxic" agent, as in an hemolytic anemia observed in rats following splenectomy, "inclusion bodies" have been reported in association with methemoglobin formation.⁸

Nevertheless, a "cause and effect" relationship between methemoglobin and "inclusion body" erythrocytes has been questioned. The appearance of "inclusion bodies" in the peripheral blood does not always follow methemoglobin formation.^{8, 14}

In one investigation, the "agent," rather than the methemoglobin per se, was found to be the more important factor in the concentration of "inclusion bodies" in the blood. Thus, the nitrates, which form less methemoglobin than the nitrites, have produced many more inclusion bodies.¹²

Observations⁸ in eleven patients with acute poisoning from aniline or nitroderivatives have revealed that "inclusion bodies" appear only several hours after methemoglobin is formed. Moreover, several more hours may elapse, as noted in a schizophrenic who had swallowed one-half glass of aniline, before these bodies become prominent and involve a maximum number of the mature circulating red cells, even to 100 per cent. In this patient, massive hemolysis of the red blood cells was noted on the fifth day and "inclusion bodies" were seen extruding in various stages from hemolyzing red blood cells. Immediately after, there occurred a reticulocyte crisis with normoblastosis.⁸

Since 1943 there have appeared several reports in the German literature of sulfonamide drug anemia preceded by the appearance of inclusion-containing erythrocytes.¹⁴⁻¹⁷ It has been advised that if more than 20 per cent appear, a severe hemolytic anemia may be forecast, and the drug should be forthwith discontinued.¹⁴

SUMMARY

1 "Inclusion bodies," distinguishable from the Howell-Jolly bodies, were observed in the red blood cells of a patient with a severe refractory fatal anemia, who had been receiving erythrol tetranitrate over a period of one year.

2 "Bodies" with similar staining characteristics were reproduced in cats with large oral doses of erythrol tetranitrate and other nitrates. These were generally accompanied by a temporary fall in the red cell count, followed by recovery upon withdrawal of the drug.

aged Plasma volume and red cell volume were done by T-1824 and venous hematocrit, serum proteins by the Howe method The main results are given in table 1

In the sprue patient the hematologic response took place while the patient was in negative nitrogen balance, in the pernicious anemia case positive N balance and blood response coincided

The plasma N did not increase significantly, the rise in hemoglobin N represents a transfer from bone marrow to peripheral circulation

It is of interest that in both cases positive balance was established and creatinuria

From the Department of Medicine College of Physicians and Surgeons, Columbia University and the Presbyterian Hospital in the City of New York

lessened In the pernicious anemia patient this occurred without change in N or caloric intake, in the sprue case appetite made increased diet essential to satisfy the patient

Mosenthal¹ in 1918 showed that the forced feeding of a diet rich in meats restored nitrogen balance in pernicious anemia

The present studies were undertaken to determine whether the positive nitrogen balance appeared before the hematologic response following liver therapy If this had occurred it might indicate that an important site of action of liver extract was on the gut wall This, however, was not the case, and liver extract presumably acts directly on the immature red cells in the marrow cavity

THE PATHOGENESIS OF ANEMIA IN ACUTE GLOMERULONEPHRITIS ESTIMATIONS OF BLOOD PRODUCTION AND BLOOD DESTRUCTION IN A CASE RECEIVING MASSIVE TRANSFUSIONS*

By CHARLES P. EMERSON, M D

ANEMIA is one of the familiar manifestations of Bright's disease and a frequent complication of uremia, irrespective of the etiologic factors responsible for renal failure ¹⁻³ A peculiarly intimate association exists between anemia and glomerulonephritis, in relation to which this hematologic sign is of diagnostic and prognostic importance ⁴⁻⁵ Conclusions regarding its pathogenesis are based on the experience of numerous investigators, who have emphasized the consistent lack of signs indicating excessive blood loss or blood destruction, and have succeeded in correlating the occurrence and severity of this anemia with the degree and duration of associated azotemia ^{2-4, 6-7} Hence, the anemia associated with nitrogen retention is generally regarded as an example of erythropoietic failure Furthermore, its refractoriness to erythropoietic stimulation with iron or liver therapy has been interpreted ⁸⁻¹¹ as evidence that blood production in patients with renal decompensation is retarded in consequence of 'toxic inhibition of the bone marrow' by retained nitrogenous metabolic products

This hypothesis, although possibly correct, as a premise mainly deduced through analogy, by inference and by exclusion bears particular scrutiny, little or no evidence of a positive and unequivocal sort having been marshalled in its support The toxic metabolite presumed to be implicated has thus far escaped identification, and of all of the numerous chemical agents recognized as bone marrow depressants there is none known to exert comparable effects on the bone marrow or peripheral blood Finally, it may be objected that the hematologic data cited from case reports in support of this concept, including descriptions of reticulocytosis and alterations of bone marrow histology, ^{5, 12-14} in some instances suggest an enhancement, rather than a depression, of erythropoietic activity in patients with nephritis and anemia

Transfusion studies, designed to permit an estimation of the survival of injected donor red cells, have contributed valuable information relative to the pathogenesis of various types of anemia, particularly those associated with certain hemolytic syndromes ¹⁵⁻¹⁶ This technic of investigation, employing serial measurements of the circulating blood volume in addition to selective agglutination counts, was applied in the study of a patient with an initial attack of early acute glomerulonephritis, who, presenting signs of moderate azotemia and progressive anemia, was adjudged particularly suitable as a subject for detailed hematologic investigation Data were accordingly obtained which served as a basis for the relative evaluation of blood production, blood loss and blood destruction as factors possibly implicated in the development of his anemia Appreciating the limited significance of the results obtained, which, pending confirmation from comparable investigations can

*The data utilized in this case report were obtained while on active duty with the Fifth (U S) General Hospital in the European Theater of Operations

hardly be evaluated in relation to other patients with Bright's disease, the observations are nevertheless considered of sufficient interest to warrant description in the form of an individual case report

CASE HISTORY AND INITIAL OBSERVATIONS*

A 27-year-old, white, American enlisted soldier was admitted to the hospital complaining of progressive swelling of the legs. Two months before entry he had contracted an acute pharyngitis which completely subsided in the course of several days. Thereafter he experienced persistent weakness and unusual fatigability. Two weeks before admission he became aware of painless swelling of his lower extremities, which increased, and, together with symptoms of general malaise, headaches and anorexia, occasioned his entry to the hospital.

The physical findings on admission were those of a well-developed male with pallid complexion and obvious pitting edema of the lower extremities. His body temperature was normal, arterial pressure 190/130 mm Hg, height 168 cm, weight 73.4 Kg (13 Kg in excess of his average weight prior to the present illness).

Initial laboratory data. Urinalysis: Specific gravity 1.015, albumin 4+, sediment (uncentrifuged) containing 15-20 r b c, 2-4 w b c and numerous casts, granular and cellular per high power field. Blood hemoglobin concentration, 13.1 Gm per cent, red cell count, 3.98 million per cu mm, hematocrit reading, 36.7, leukocytes, 8,200 per cu mm, with normal differential count, platelets, 294,000 per cu mm. Erythrocyte osmotic fragility normal, sedimentation rate (Westergren) 17 mm in one hour. Blood urea nitrogen concentration, 25 mg per cent, total serum protein concentration, 4.4 Gm per cent. Bleeding time (Duke) 3½ minutes, clotting time (Lee-White) 8½ minutes. Stool examinations were negative for occult blood. The initial throat culture contained beta hemolytic streptococci, this organism failing to be demonstrated on re-examination after eight days.

METHODS OF STUDY

The patient was observed for a period of fifty days during which he was essentially at complete bed rest, maintained on a dietary regime restricted solely with respect to its sodium content. Penicillin, 120,000 units daily, was administered intramuscularly from the fourth to the thirteenth day. Otherwise, apart from transfusions and albumin injections subsequently to be specified, no therapeutic agents, hemopoietic, diuretic or antibacterial, were employed.

Daily observations included measurements of the arterial pressure, body weight, fluid intake and urine volume. Urinalyses were performed daily, which included, after the eighth day, a quantitative (Esbach) estimation of the total urine albumin excretion. Blood hemoglobin concentrations and icterus indices were determined with Klett photoelectric technics. Blood urea nitrogen was measured colorimetrically after urease digestion and nesslerization, and total protein concentrations by the procedure of Phillips and Van Slyke.¹⁷ Plasma volume determinations, employing T-1824 dye, were performed by a modification¹⁸ of the method of Gibson and Evans.¹⁹ Calculations of the circulating red cell volume and total blood volume were based on the plasma volume and hematocrit values, these computations involving a correction factor of -15 per cent applied to the calculated red cell volume to compensate for the relatively constant disparity between the large vessel hematocrit and the total body hematocrit.²⁰

Group-O donor blood, freshly drawn into acidified glucose-citrate anticoagulant

*Identifying initials of the patient have been deleted here and in the table and figures at the request of the Technical Information Office of the Surgeon General's Office.

solution, was employed in the first course of transfusions, in preparation for the second series red cells from freshly obtained group-O blood were washed once and resuspended in 0.85 per cent saline solution. At intervals following transfusions the concentration of donor cells was determined, from these data it was possible to calculate the total volume of circulating donor cells and group-A recipient's cells. Selective agglutination counts were performed by modifications of the Ashby technic, utilizing dried anti-A grouping serum, a procedure that has been successfully applied in other investigations^{21, 22} and has recently been evaluated by Young²³

FIG 1 Hematologic, blood chemical, and clinical data on a case of acute glomerulonephritis receiving infusions of whole blood, red cells and albumin

COURSE

The hematologic findings and metabolic data obtained in this case are charted in figure 1 which depicts the observed fluctuations in the hemoglobin concentration, red cell count, blood urea nitrogen, total serum protein concentration, fluid balance, total albumin excretion, body weight and systolic arterial pressure

It was evident on the fifteenth day that the patient's anemia, which was of a normocytic, normochromic type, was progressing in severity, the hemoglobin concentration having decreased from 13.1 to 11.2 Gm per cent and the hematocrit reading from 36.7 to 30.8 since admission to the hospital. Blood volume measurements (table 1 and figure 2) indicated a total circulating red cell volume of 1080 cc representing a calculated deficit of approximately 900 cc or 45 per cent, relative to

the expected volume for an average normal male of his stature. The total blood volume was likewise deficient (approximately 20 per cent), this decrease being en-

FIG. 2. The influence of blood transfusions on anemia associated with acute glomerulonephritis

tirely accounted for on the basis of the decrease in red cell volume, the plasma volume being within normal limits. Blood loss via the gastrointestinal and renal

tracts had been insignificant, hematuria continuing to be of microscopic degree, and only an occasional stool containing a trace of occult blood during the entire period of observation.

First transfusion series On the fifteenth, and again on the sixteenth hospital day the patient received group-O whole blood totalling 470 cc of red cells and 650 cc of plasma. A mild febrile reaction followed on each occasion and, at the conclusion of the second injection, he experienced transient severe lumbar aching pain. The spleen promptly became enlarged and remained palpable for two weeks. Hemoglobinemia and hemoglobinuria did not occur, but there developed for the first time a mild transient icterus, a relative decrease in urine output and an increase in albumin excretion.

Blood volume studies and selective agglutination counts performed on the day following the second transfusion demonstrated that, whereas the injected red cells had survived *in toto*, a destruction of the patient's group-A cells had occurred, this loss approximately equalling the volume of transfused erythrocytes (table 1 and fig. 2). Thereafter, during the nine day interval between the first and second series of transfusions, the red cell volume continued to diminish, the patient's cells decreasing by 100 cc (15 per cent) and the donor cells by 120 cc (27 per cent). This progression of anemia developed despite the onset of a persistent reticulocytosis which occurred abruptly following transfusion (fig. 2).

Second transfusion series Between the twenty-fifth and twenty-ninth hospital days the patient was transfused with saline-washed group-O cells derived from 2000 cc of whole blood, all plasma having been removed. The total red cell volume was thereby increased to 1610 cc, or approximately 80 per cent of the expected normal value. There was a recurrence of mild transient icterus which, on the basis of selective agglutination counts, was apparently due to the prompt destruction of those donor cells injected in the final transfusion. No destruction of patient's cells resulted and those donor cells remaining at the conclusion of this series of transfusions survived thereafter in normal fashion, less than 10 per cent being eliminated in the course of the ensuing two weeks. A progressive increase in the patient's circulating red cells was demonstrable after the twenty-fifth day, their total volume being 250 cc, or 45 per cent, greater on the forty-third day. Although no subjective symptoms were associated with the cell transfusions a definite increase in proteinuria was noted immediately thereafter, a phenomenon which had likewise followed the earlier transfusions of whole blood, and the subsequent administration of crystalline human albumin.

DISCUSSION

This report concerns a patient hospitalized early in an initial attack of acute glomerulonephritis with manifestations of arterial hypertension, hematuria, albuminuria and nitrogen retention, who was under continuous observation for fifty days. During the first observation period, when renal decompensation was maximal, although by no means marked, there developed a moderately severe normocytic normochromic anemia of a type commonly associated with nephritis. Two weeks following the appearance of dependent edema, the first clinical evidence of

his renal disease, the venous hematocrit reading was 36.7, a reduction of approximately 20 per cent, two weeks later the hematocrit was 30.8, approximately 30 per cent below normal, but the calculated deficit in total circulating red cell volume at this time was 45 per cent. Measurements of the plasma volume indicated that there had occurred no compensatory increase in the latter, and that the true severity of the anemia, judged solely on the basis of the red cell and hemoglobin concentrations, had been obscured as a result of a reduction in the total blood volume. Alterations of a similar character in patients with acute nephritis have been reported by Harris and Gibson.²⁵

Rapid red cell depletion of the degree exhibited by this patient is difficult to explain solely on the basis of erythropoietic depression due to toxic inhibition of the bone marrow, to a metabolic defect, or to a nutritional deficiency. Even assuming a complete cessation of blood production the decline in the red cell volume occurred at approximately twice the expected rate²⁶ of 0.8 to 1.0 per cent per day, unless this bone marrow aplasia is considered to have occurred at the time of the antecedent pharyngitis. The latter possibility can hardly be discarded, but such an hypothesis presumes that the initial observations of hematocrit and hemoglobin concentration were misleading, the plasma volume at that time being considerably lower than when first determined two weeks later, a supposition for which there is no basis. Complete bone marrow inactivity is in any case an improbable explanation for the observed anemia, on the grounds that the reticulocytes, although not numerous (1.2 per cent) before transfusion therapy, were nevertheless present. It is of interest that the presence of reticulocytes in the peripheral blood has consistently been described in case reports published in relation to this problem, whatever interpretations may have been adduced from the hematologic data obtained.

Significant blood loss having been adequately excluded during the entire period of observation, it is inferred that excessive and uncompensated blood destruction must have been responsible for the rapid development of anemia in this case. Observations following the first series of transfusions tended to confirm this evaluation of the mechanisms involved. The patient, blood group-A, received 1000 cc of group-O whole blood in the course of twenty-four hours, a procedure which precipitated a mild hemolytic crisis, with prompt destruction of 430 cc of his own cells. Inasmuch as the donor erythrocytes quantitatively replaced the destroyed recipient cells there occurred no significant change in the severity of the anemia. An important contributing factor in this response was unquestionably the presence of incompatible isoagglutinins in the injected donor blood, the hemolytic effect of which has been previously described. Unfortunately the titer of anti-A isoagglutinins in the injected material was not determined. It may be stated, however, that no instance has been observed²¹ in which a comparable degree of hemolysis was produced by the first transfusion of plasma or whole blood containing incompatible isoagglutinins in very high titer, hence this patient must have been unusually susceptible to the hemolytic effect of the "universal donor" blood he received. Of far greater significance are the observations pertaining to the subsequent fate of the normal donor erythrocytes which were eliminated at an average rate of 3 per cent per day, or more than three times the expected rate. Depletion of the patient's own

cell population also continued to be excessive (1.6 per cent per day) but their net loss occurred less rapidly, which may be explained on the basis of a sudden increase in blood production evidenced by a concomitant reticulocytosis (fig. 2)

This sudden and unexpected increase in reticulocytes, indicating enhanced erythropoietic activity immediately following transfusion, deserves particular mention. Immediately preceding this therapy the reticulocyte count was 1.2 per cent, immediately thereafter the percentage had increased to 13.8. The precise explanation for this phenomenon is not evident, but it is of interest that the peak reticulocytosis occurred prior to a further substantial reduction in the venous hematocrit or hemoglobin concentration, hence, the stimulus for increased bone marrow activity was not primarily an increase in bone marrow hypoxia. Moreover, inasmuch as it occurred at a time when the elevation of blood urea nitrogen was almost maximal, one is tempted to reject the hypothesis that the previous inadequacy of blood production was due to toxic inhibition of the bone marrow as a result of nitrogen retention or to other unexcreted metabolites. It is possible that the resumption of normal erythropoietic activity displayed at this time was related to the increased hemolysis provoked by the administration of incompatible isoagglutinins, that it occurred, not as a result of increased anemia, donor erythrocytes having been substituted almost quantitatively for the patient's hemolyzed red cells, but due to the stimulus of some hemopoietically effective material derived from the latter. Or the donor blood may have been the source of an erythropoietic agent, of which there had been a previous deficiency. Whatever the true explanation, blood formation proceeded thenceforth at an increased rate, although temporarily outpaced by blood destruction.

As a result of the second series of transfusions, involving the administration of plasma-free red cell suspensions, the patient's anemia was practically relieved. In the course of four days the hemoglobin concentration was increased from 9.3 to 15.3 Gm per cent, and the hematocrit reading from 27.1 to 43.7, the total red cell volume was almost doubled. A significant proportion of the injected cells were hemolyzed in the process of their preparation, or were eliminated very promptly following the injection. Nevertheless the subsequent fate of this donor blood, which survived normally, together with data indicating a progressive increase in the patient's red cell population, suggest that abnormal blood destruction had ceased, and that blood formation was occurring at a normal rate. The factors responsible for this reversion to a normal hematologic status can not be positively identified on the basis of the available evidence. It is of interest, however, in view of the well known correlation between the anemia of renal disease and the degree of nitrogen retention, that during the first twenty hospital days when signs of increased blood destruction and impaired erythropoiesis were most prominent, the blood urea nitrogen concentration ranged from 25 to 34 mg per cent (average 30 mg per cent), whereas during the subsequent thirty days when erythropoiesis and hemolysis were normal the blood urea nitrogen did not exceed 20 mg per cent (average value 17.5 mg per cent). No relationship was observed between the hematologic status and the grade of hematuria and proteinuria, or fluctuations in the total circulating protein.

A final comment is warranted regarding the influence of transfusion therapy on other manifestations of nephritis in this case. No evidence can be adduced that the course of the arterial hypertension, which was one of gradual improvement, was in any way affected by these maneuvers. Hematuria and albuminuria persisted without remission throughout the period of study. The transient elevations of total urinary albumin excretion following each series of transfusions, whether involving the injection of whole blood, washed red cells or purified albumin, presumably reflect an increased renal blood flow and glomerular filtration attending this therapy. Similar increases in proteinuria following the administration of albumin in cases of nephritis have been described by Thorn et al.²⁷ The progressive improvement in renal function as measured by changes in body weight, indicating increasingly effective water and sodium clearance, is readily attributable to the natural course of this patient's disease, rather than to variations in the degree of anemia. Thus, there was less water retention on the twenty-fifth hospital day, when his body weight was 69 kilograms, his blood volume 3650 cc and hematocrit 27.1, than on the fourteenth day when his body weight was 73 kilograms, blood volume 3960 cc and hematocrit 30.8. Similar conclusions obtain with respect to the observed reduction, between the eighteenth and twenty-first days, in the blood urea nitrogen concentration, these data being obtained in a patient whose renal decompensation was never severe, and whose clinical course was entirely consistent with one of progressive spontaneous improvement.

SUMMARY AND CONCLUSIONS

1. A 27 year old patient with an initial episode of acute glomerulonephritis was observed over a fifty day period, studies being directed primarily in an attempt to define the mechanisms responsible for a rapidly developing anemia. Hematologic data, including serial blood volume measurements and selective agglutination counts were obtained before and after the introduction of massive transfusion therapy.

2. The administration of group-O whole blood containing incompatible anti-A isoagglutinins in the first series of transfusions failed to improve the anemia but initiated a sustained reticulocyte response. Following this therapy there was evidence of increased blood destruction involving both the recipient's and the normal donor erythrocytes.

3. Data obtained following a second series of transfusions employing plasma-free group-O red cells, administered during a recovery phase when renal function had improved, indicated that blood destruction had largely abated and that hemopoietic activity was normal.

4. Two factors of undetermined origin are believed to have been implicated in the pathogenesis of anemia in this case: one, the occurrence of abnormally rapid blood destruction, and the other, impairment of blood formation. Both phenomena were associated with the presence of nitrogen retention, despite which, however, a prompt erythropoietic response followed the transfusion of whole blood with quantitative replacement of patient's red cells with donor erythrocytes, suggesting that previous bone marrow inactivity was not attributable to "toxic suppression."

STUDIES ON THE DESTRUCTION OF RED BLOOD CELLS * IV

THEMAL INJURY ACTION OF HEAT IN CAUSING INCREASED SPHEROIDICITY, OSMOTIC AND MECHANICAL FRAGILITIES AND HEMOLYSIS OF ERYTHROCYTES, OBSERVATIONS ON THE MECHANISMS OF DESTRUCTION OF SUCH ERYTHROCYTES IN DOGS AND IN A PATIENT WITH A FATAL THERMAL BURN

By THOMAS HALE HAM, M D , SHU CHU SHEN, M D , ELEANOR M FLEMING, A B ,
AND W B CASTLE, M D

IN A PREVIOUS communication¹ observations were reported on the changes in blood and urine and on the kidney complications occurring in 14 patients with moderate or severe thermal burns, 11 of whom showed hemoglobinuria. The spherocytosis and increased osmotic fragility of the red blood cells, observed in certain of these cases, were considered to result directly from the heating of the circulating blood. This paper reports detailed observations on the effect of heat on human erythrocytes and on the mechanism of destruction of heated dog red blood cells following their injection into the same animal. Finally, the characteristics of the red blood cells are reported in an additional case of a fatal thermal burn.

Previous investigations have established certain fundamental facts concerning the effect of heating red blood cells in the test tube and in the animal as a result of thermal burns. There is agreement²⁻⁷ with the original observation of Schultze⁸ that the heating of blood in vitro from human subjects, dogs, cats, and rabbits to temperatures of from approximately 52 to 65 C produces division and fragmentation of erythrocytes with the formation of spheroid forms of various sizes. In anesthetized animals, subcutaneous temperatures of from 51 to 65 C have been maintained for several minutes by scalding,⁹ by igniting turpentine on the skin,¹⁰ or by use of a hot iron.¹¹ Furthermore, it has been demonstrated,^{10 12 13} especially by von Lesser,² that fragmented erythrocytes occurred in the blood stream in burned animals, in normal animals transfused with blood from a burned animal, and in normal animals transfused with blood heated in vitro. The abnormal erythrocytes disappeared rapidly² from the animal's circulation with the development of hemoglobinemia and hemoglobinuria. No hemolysins or agglutinins have been demonstrated in the plasma or serum of burned animals⁵ or of burned patients.¹ An increase in the osmotic fragility of the red blood cells was noted in burned animals by Silberman³ and in human blood heated in vitro by Isaacs, Brock, and Minot.⁷ The latter investigators demonstrated that immature erythrocytes of both normal and pathologic human blood divided less readily than mature erythrocytes, when heated to 55 C. More recently hemoglobinemia, hemoglobinuria, fragmentation of erythrocytes, and increase in the osmotic fragility of red cells have been reported in a series of cases of human thermal burns by Brown^{14 15} and in animals subjected to

thermal injury by Moritz, Henriques, and Dutra¹⁶ and by McLean, Moritz, and Roos¹⁷ Hemoglobinemia and increased blood destruction have been observed as an early manifestation of severe burns in human subjects by Moore, Peacock, Blakely, and Cope¹⁸ and in burned animals by Olson and Necheles¹⁹

METHODS

The methods employed in this investigation have been described in previous communications as follows: determination of osmotic fragility of red blood cells¹, determination of mechanical fragility of red blood cells²⁰, estimation of the number of 'spherocytes' in a stained smear¹, determination of hematocrit²¹, quantitative estimation of hemoglobin in plasma and urine²²⁻²⁴, measurement of pH of blood and urine by glass electrode method, measurement of methemoglobin and sulphhemoglobin²

EFFECT OF HEAT ON ERYTHROCYTES

Changes in the shape, osmotic fragility, and volume of red cells were measured in 131 observations in defibrinated blood from 12 normal persons and from dogs. The blood was exposed to temperatures of from 25 to 70 C maintained for periods of from two minutes to one hour. All blood samples were heated, usually in 5 or 6 cc amounts, in soft glass test tubes of 13 mm diameter by 250 mm length. For larger volumes, pyrex Erlenmeyer flasks were employed. Each blood sample was first placed in a water bath at 37 C until this temperature was attained. Then the sample was immersed in a bath containing 30 liters of water which was agitated by a mechanical stirrer, and maintained at constant temperature with an accuracy of ± 0.05 C. A precision thermometer was introduced directly into the blood sample as it was heated and the temperature recorded every fifteen seconds, usually during gentle mixing with the thermometer. The blood sample was heated from 37 C to a particular temperature in approximately 2½ minutes, and maintained for a given time within ± 0.05 C at the required temperature. The sample was then removed from the bath and promptly cooled to 37 C in a water bath. The rates of heating and cooling were approximately equal. For the so-called "rapid heating" the water bath temperature was set 0.7 C above the final temperature desired for the blood sample. It required from one to two minutes in each observation to reach the desired temperature, at which time the blood was immediately removed and cooled as described above. Unheated and heated samples were compared with respect to hemolysis, osmotic fragility and shape of the red blood cells, hematocrit, pH, methemoglobin, sulphhemoglobin, and nonprotein nitrogen.

The changes produced in the red blood cells appeared in the following order: morphologic changes, apparent increase in volume, increase in osmotic and mechanical fragilities, and finally hemolysis in the serum or plasma. Temperatures up to 46 C for a period of one hour caused no demonstrable changes in the erythrocytes. At temperatures from 47 to 50 C changes in the red blood cells occurred depending on the temperature and duration of heating. At temperatures of from 51 to 65 C, changes always occurred even when the sample was subjected to "rapid heating." Changes occurred in dog red cells similar to those observed in human red cells. The various effects produced by heat are described separately below.

A CHANGES IN MORPHOLOGY OF ERYTHROCYTES PRODUCED BY HEAT

The morphology of the red blood cells was studied in wet preparations made by diluting defibrinated blood with serum, physiologic saline, or Gower's solution and introducing one drop into a standard blood counting chamber or onto a glass slide, covering it with a glass coverslip and sealing with vaseline. In fixed preparations stained with Wright's stain, the red cells were examined for changes in size and shape, including the presence of "spherocytes" and "target" forms. The diameter of the red blood cells before and after heating was measured in stained preparations by the Price-Jones²⁶ method. Because of the bizarre forms produced by heating, these measurements serve only as an approximation.

* Quantitative measurement was not possible

† Rough approximation

At temperatures of from 48.6 to 49.6 C, it was possible to observe the slow progression of the morphologic changes in the erythrocytes. A typical experiment conducted with heating of defibrinated blood at a constant temperature of 48.6 C for 2, 5, 10, 30, and 60 minutes, respectively, is illustrated in table 1 and figure 1. The first discernible change produced by heat was the appearance of small bud-like protrusions on an occasional erythrocyte. In the next recognizable change, many of the erythrocytes showed single or multiple buds usually connected by a broad base or a filament. When completely disconnected, the new elements formed small rounded or elongated structures containing various amounts of hemoglobin. At this stage, as illustrated in figure 1B and table 1 (2 and 5 minutes), there was no change in osmotic fragility of the red blood cells but apparent increases in hematocrit of 3.2 to 5.9 per cent, respectively. It is possible that the increase in hematocrit

in this and subsequent experiments did not represent a true swelling of the erythrocytes, but rather an inability to pack the malformed erythrocytes by centrifugation at 3000 r p m. This apparent increase in hematocrit occurred simultaneously with morphologic alteration of the erythrocytes, increased slightly with their progres

FIG. 1. EFFECT OF HEAT ON MORPHOLOGY OF RED BLOOD CELLS

A, upper left, unheated human defibrinated blood. Other samples heated at a temperature of 48.6°C, B, upper right, for 5 minutes, C, lower left, for 10 minutes, D, lower right, for 30 minutes. Stained blood films $\times 1000$ (See table 1).

sive alteration, and thereafter did not vary in parallel with the increase in osmotic fragility. This phenomenon was not investigated further.

The first increase in osmotic fragility occurred after still further fragmentation of erythrocytes and coincidentally with the appearance of significant numbers of densely staining red cells of various sizes which appeared spheroid in shape in wet preparations and densely stained in fixed smears, as may be seen in figure 1C and table 1 (10 minutes). Continued fragmentation, as illustrated in figure 1D, resulted in the conversion of the majority of erythrocytes to spheroid cells, occasional

"ghosts," and many polymorphic fragments varying in size from 1-2 microns down to innumerable minute particles approximately the size of bacteria showing active Brownian movement in wet preparation. Microscopic examination of the erythrocytes in a wet preparation did not reveal Heinz-Ehrlich bodies^{27, 28}

B CHANGES IN OSMOTIC FRAGILITY OF ERYTHROCYTES PRODUCED BY HEAT

Coincident with the continued fragmentation of erythrocytes, the osmotic fragility became significantly increased. The production of spheroid erythrocytes was evident from inspection of wet preparations and from the decrease in diameter and dense staining of red blood cells in stained preparations. As shown in table 1 (30 and 60 minutes), the increased osmotic fragility was also associated with a decrease in the mean diameter of the erythrocytes and an increase in the coefficient of variation of the diameters. It should be emphasized that progressive fragmentation of the erythrocytes occurred without significant loss of hemoglobin unless the osmotic fragility of a portion of the population had increased to such an extent that hemolysis occurred in concentrations of sodium chloride of from 0.85 to 1.0 grams per cent. Thus, when the osmotic fragility was normal, the free hemoglobin in the plasma was less than 1 per cent of that contained by the cells of the sample, this was also observed in many instances when both fragmentation and fragility were greatly increased, as shown in table 1 and in table 2. However, with sufficient heating, the osmotic fragility of the red cells could be so increased as to produce marked hemolysis of cells in serum or plasma. Thus, "rapid heating" at temperatures of from 55 to 60 C produced up to 5 per cent hemolysis, at temperatures of from 62 to 65 C from 22.5 to 100 per cent hemolysis.

In contrast to the morphologic changes in erythrocytes which were heterogeneous and difficult to evaluate quantitatively, the changes in osmotic fragility produced by heating were definitive and readily measured, as shown in figure 2. The change in osmotic fragility caused by a particular temperature and period of heating was remarkably reproducible for blood samples obtained at the same time or at different times from normal persons. When different blood samples were heated for a fixed period of time, a critical temperature was found, above which an increase of from only 1.0 to 1.6 C produced a phase of rapidly increasing osmotic fragility, as illustrated in figure 2 and table 2. Below this critical temperature range, the osmotic fragility was always found to be normal. For example, rapidly increasing osmotic fragility values occurred for "rapid heating" between 50.6 and 51.6 C, and for a period of sixty minutes of heating between approximately 47 and 48.6 C. Moderate and similar increases in osmotic fragility were produced by the following temperatures and periods of heating: at approximately 50.8 C by "rapid heating," and at approximately 49.2, 49, 48.6, 48.4, and 48 C by 2, 5, 10, 30, and 60 minutes heating, respectively. In order to illustrate the reciprocal relation between the effects of temperature and the duration of heating sufficient to produce a given increase in osmotic fragility, these data were plotted in two ways in figure 3. The approximately straight line function between the reciprocal of the absolute temperature and the logarithm of the time (equivalent to the rate), to be seen in figure 3B, suggests the conformity of enzyme reactions or chains of reactions with Ar-

rhénus' law²⁹ No attempt was made to interpret these data further Henriques³⁰ has made a mathematical analysis of experimental time temperature relationships for thresholds of epidermal injury

Observations were made of the changes in morphology and osmotic fragility produced by the heating of blood samples containing abnormally spheroid red cells from patients with chronic hypochromic anemia and sickle cell anemia, respectively The results are summarized in table 3 In each instance, experimental conditions were arranged so that the heating of the blood sample increased the osmotic fragility of the red cells to approximately the same final value The osmotic fragility of the red cells from the patient with congenital hemolytic jaundice was,

FIG. 2. OSMOTIC FRAGILITY OF RED BLOOD CELLS OF SAMPLES OF HEATED NORMAL HUMAN DEBRINATED BLOOD

of course, already increased, and, before heating, stained films showed 3 per cent of 'spherocytes' With heating, only a moderate degree of fragmentation and of decrease in mean corpuscular diameter was required to produce the observed increase in osmotic fragility On the contrary, for the relatively discoid flat, 'or target' cells with initially decreased osmotic fragility, the given degree of osmotic fragility was reached only after considerable morphologic change had appeared, indicated by marked decrease in mean corpuscular diameter and increase in the coefficient of variation of the erythrocyte diameters Paradoxically, the temperature required to produce the given degree of morphologic change was greater for the spheroid than for the discoid cells Thus, blood from the patient with congenital hemolytic jaundice required rapid heating to 52 C, that from the patient with sickle cell anemia to 50.6 C, in order to produce the same final value for osmotic fragility

fibrinated human blood was kept at a temperature of 53 C for a period of nine minutes, producing a marked increase in osmotic fragility. The heated blood and a sample of unheated blood were then centrifuged and the serums removed and interchanged in such amounts as to produce a 5 per cent suspension of heated cells in unheated serum, and the reverse. These two mixtures, together with unmanipulated samples of heated blood and unheated blood were then introduced into separate 250 cc tonometers which were closed and rotated slowly for two hours in an incubator at 37.5 C. There was no change in the abnormally increased osmotic fragility of the heated red cells produced by the fresh unheated serum and no significant hemolysis or increase in the osmotic fragility of the unheated cells suspended in the

FIG 4 Osmotic Fragility of Red Blood Cells in Mixtures of Heated and Unheated Normal Human Defibrinated Blood

N, unheated sample, 100 (per cent by volume of blood), after rapid heating to 55 C, 10-80, mixtures of varying proportions of the heated sample (10-80 per cent by volume) with the unheated sample

heated serum. When mixtures of from 10 to 80 per cent by volume of heated blood exhibiting increased osmotic fragility were made with normal blood, the resulting osmotic fragility curves showed the values to be expected from such a mixed population (fig 4).

In another experiment, a sample of plasma (containing sodium citrate 500 mg per 100 cc) and of serum were heated at 56 C for two minutes and for thirty minutes, respectively. The precipitated fibrin was then removed from the heated plasma by centrifugation. Five per cent suspensions of unheated red cells were then made in each and were incubated in tonometers as described above, for the same time as unheated samples of whole citrated and defibrinated blood. No significant changes occurred in the osmotic fragility or degree of hemolysis of any of the six samples.

The effect of different mediums on the increases in osmotic fragility of red cells

caused by heat was investigated. Whole blood containing heparin, 150 mg per 100 cc, defibrinated blood, and red cells from defibrinated blood washed and resuspended in isotonic salt solution, were heated for ten minutes in separate test tubes under identical conditions. At 48.8°C, a moderate and similar increase in osmotic fragility was produced in each. At 49.6°C, however, the red cells in isotonic saline showed a somewhat greater increase in fragility and a significantly greater degree of hemolysis, 16 per cent, compared to 2 and 1 per cent, respectively, for the other two samples. Similarly, washed red cells suspended in isotonic saline, when heated up to 53°C in three minutes, showed a greater increase in osmotic fragility than did the red cells from defibrinated blood that was treated similarly. Hemolysis of the red cells in isotonic saline was 34 per cent, but only 2 per cent in defibrinated blood. However, when the red cells of the heated defibrinated blood sample were washed and resuspended in isotonic saline, they exhibited the same increase in osmotic fragility as those originally heated in suspension in saline. In contrast to heparin, sodium citrate, 250 mg per 100 cc, when used as anticoagulant for whole blood or when added to defibrinated blood caused a significantly greater increase in fragility and in hemolysis when the samples were heated than was observed with heated defibrinated blood. The possible effect of other salts was not investigated.

The increase in osmotic fragility of the red cells was not accompanied by any significant change in the nonprotein nitrogen concentration of heated defibrinated blood or of erythrocytes washed and suspended in isotonic sodium chloride solution. There was no production of methemoglobin or sulphemoglobin. The hydrogen ion concentration of the suspension of red cells, as measured by the glass electrode, was not materially changed for heated whole blood containing heparin or sodium citrate 250 mg per 100 cc, for defibrinated blood, or for erythrocytes washed and suspended in isotonic saline.

D. EQUILIBRIUM VOLUMES OF HEATED ERYTHROCYTES

The equilibrium volume of erythrocytes (hematocrit) from samples of normal and heated human defibrinated blood was tested by a modification of the method of Castle and Daland³¹ who emphasize the fact that differences in osmotic fragility of different types of erythrocytes are not explained by differences in strictly osmotic properties, but rather by differences in the shape of red cells. The purpose of these experiments was to determine what alterations, if any, were produced by heat in the permeability of the membrane of the red cell or in the osmotic activity of its contents. Because no striking changes in the hematocrit of samples of defibrinated blood were noted to occur as a result of heat, such effects appeared to be minimal.

Aliquot samples of human defibrinated blood were heated rapidly to 49.6 and 50.6°C, thus producing a slight and an extreme increase in osmotic fragility, respectively, as shown in table 4. Then 1.0 cc amounts of these two samples and of an unheated aliquot were mixed with 1.0 cc amounts of solutions of sodium chloride ranging in concentration from 0.51 to 1.7 grams per cent. After mixing, the hematocrit of each sample was determined. Then the percentage difference between that value and the value obtained when the sample was mixed with sodium chloride solution 0.85 grams per cent was computed. The tonicities of the mixtures of serum

and salt solution were calculated, assuming the serum tonicity to be isotonic with 0.85 grams per cent sodium chloride solution. In the experiment shown in table 4, the original red cell volume was 48, the serum volume 52 per cent. The hematocrit readings were probably only approximate in accuracy because of the polymorphic nature of the heated red cells. Moreover, because of their increased osmotic fragility a significant portion of the heated red blood cells hemolyzed in the hypotonic mixtures of sodium chloride. In the hypertonic solutions, however, hemolysis did

* Serum was considered to have a tonicity equivalent to NaCl, 0.85 Gm per cent

not occur and the percentage decrease in hematocrit was roughly the same for the heated and unheated sample. This indicates that, as with red cells of naturally occurring different osmotic fragilities, the strictly osmotic behavior (percentage change in equilibrium volume with change in tonicity of suspension medium) of the heated red cells did not differ significantly from that of the normal red cells.

B. EFFECT ON HEATED ERYTHROCYTES OF SUBSEQUENT INCUBATION AT 37.5 C

Samples of normal human and dog defibrinated blood were so heated as to produce a moderate increase in osmotic fragility. Then 6 cc amounts of heated and un-

heated samples of each were incubated in 250 cc tonometers with slow rotation at 37.5 C for periods of 4, 8, or 10 hours. A significant increase occurred in the osmotic fragility of the heated, compared to the unheated, samples of dog blood. The increases in the osmotic fragility of the heated human red cells were minimal even after ten hours, as were those of the unheated controls. This corresponds with previous observations^{32, 33} upon the sterile incubation of normal and pathologic human blood and indicates, apparently, an increased susceptibility of the heated dog red cells to such incubation.

F CHANGES IN MECHANICAL FRAGILITY OF ERYTHROCYTES PRODUCED BY HEAT

The mechanical fragility of samples of both heated and unheated human and dog blood was determined. For example, samples of defibrinated dog blood were subjected to "rapid heating" at 49.8, 52.8, and 54 C. Immediately thereafter, the hematocrit and osmotic fragility of each of the heated bloods were determined. The hematocrits of the unheated samples were adjusted by removal of serum to equal those of the samples exposed to the highest temperature. The hematocrits of the other heated samples were not adjusted in each experiment. The mechanical fragility of a given sample was taken as the percentage of its hemoglobin liberated by standardized trauma from glass beads rolling in a rotating tonometer.²⁰

Heating of blood that was just insufficient to cause increase in osmotic fragility had no detectable effect on mechanical fragility. However, the effect of sufficient heat was to produce progressive increases in both the osmotic and mechanical fragilities of the erythrocytes. The increase in mechanical fragility was roughly proportional to the increase in osmotic fragility. Thus, for example, as may be seen from figure 5, rapid heating to temperatures of 52.8 and 54 C caused the mechanical fragility of a sample of dog blood to increase from a control value of 7.0 per cent to 20.2 and 31.5 per cent, respectively. A temperature of 52.2 C caused the mechanical fragility of a sample of human blood to increase from a control value of 3.9 per cent to 16.3 per cent (no figure shown).

Continuous trauma of heated defibrinated human or dog blood for periods of from three to eight hours apparently did not destroy selectively those red cells that showed the greatest increase in osmotic fragility. This was evidenced by observation of the curve of osmotic fragility at frequent intervals while hemolysis from trauma was progressing. With human blood there was no evident change in shape of the osmotic fragility curve to indicate alteration of all or selective destruction of any particular portion of the cell population. On the contrary, samples of defibrinated dog blood that were heated sufficiently to produce increased osmotic and mechanical fragility of the red cells when subjected to continuous trauma for fifty minutes or at intervals for three hours, showed a significant uniform and progressive increase in osmotic fragility as the hemolysis from trauma increased. It was assumed, as a hypothesis without further investigation, that the progressive increase in osmotic fragility resulting from the continuing trauma of heated dog blood might be the result of an increase in the degree of fragmentation of the red cells already initiated by heat.

EFFECT OF INJECTION OF HEATED ERYTHROCYTES INTO DOGS

In previous observations¹ on patients with thermal burns, hemoglobinemia and hemoglobinuria were found. It is clear from the preceding experiments that, in blood samples heated *in vitro*, striking increases in both osmotic and mechanical fragilities of the red cells were demonstrated. In order to determine whether such red cells would be readily destroyed *in vivo*, blood was removed from normal dogs, heated, and injected into the same animal.

In the several experiments, 8 healthy dogs in the fasting state, weighing from 12 to 18 Kg, were bled, using sterile precautions, from the jugular or femoral veins

FIG 5 OSMOTIC AND MECHANICAL FRAGILITIES OF RED BLOOD CELLS OF DOGS DEFIBRINATED BLOOD AFTER 'RAPID HEATING' TO 49.8, 52.8, AND 54.0 C, RESPECTIVELY, AS INDICATED

from $\frac{1}{6}$ to $\frac{1}{3}$ of their blood volume, as estimated from their body weight.²⁴ The blood was defibrinated or citrated as drawn. In Dogs 1 and 5, ether anesthesia with an open cone was used briefly during the venesection. Immediately after the bleeding, an equal volume of isotonic sodium chloride solution containing 40 cc of molar sodium lactate was injected intravenously. The blood sample removed was treated as described below and later injected intravenously into the same animal. Thereafter, the animal was given food and water *ad libitum*. Samples of venous blood were taken at frequent intervals, before and after the injection, with precautions to prevent hemolysis of the samples by trauma.²⁴ On these samples were determined especially the morphology and osmotic fragility of the erythrocytes, the plasma hemoglobin²⁴ and the hematocrit. In experiments on Dogs 6, 7,

and 8 the mechanical fragility of the red cells was also determined. All urine samples were collected. The rectal temperature was recorded at frequent intervals.

Dog 1 received his own red cells which were heated in serum and then washed and resuspended in saline, as described below, in order to eliminate any potential hemolytic or toxic factor contained in the heated serum. From Dog 1, weighing 12 Kg, approximately $\frac{1}{3}$ of the calculated blood volume, 250 cc, was withdrawn, defibrinated, heated in a water bath at 54 C, during a period of twelve and one-half minutes required for the temperature of the blood to reach 52.2 C. The sample was then immediately cooled to body temperature, centrifuged, the serum discarded, and the red cells washed three times with 2 volumes of hypertonic (1.275 grams

FIG. 6. DOG 1. EFFECT OF INTRAVENOUS INJECTION OF WASHED RED BLOOD CELLS FROM 250 CC HEATED DEFIBRINATED DOG 1 BLOOD UPON OSMOTIC FRAGILITY OF CIRCULATING RED BLOOD CELLS.

Curve 1, Washed red cells before intravenous injection. Curve 2, immediately after injection. Curve 3, after 2 hours. Curve 4, after 7½ hours. Curve 5, after 41 hours. See also figure 7. Note that approximately 30 per cent of the red cell population was abnormal immediately after injection (curve 2). Subsequently the osmotically fragile red cells progressively disappeared.

per cent), sodium chloride solution. After the red cells were resuspended, at their original hematocrit, in the hypertonic saline, they exhibited an extreme increase in osmotic fragility as shown in curve 1 in figure 6. Immediately after the intravenous injection of the suspension, the animal's venous blood showed a mixed red blood cell population with approximately 30 per cent of cells of increased osmotic fragility and 70 per cent of normal cells, as indicated in curve 2 in figure 6. This type of mixed fragility curve resembled that occurring in artificial mixtures of heated and unheated red blood cells (see figure 4). The subsequent osmotic fragility curve showed a gradual disappearance of the osmotically fragile cells during eighteen hours after injection. Immediately after the injection of the heated red cells, although no free hemoglobin was detectable in the supernatant of a heated red cell suspension, a small amount of hemoglobin was noted in the animal's plasma and later in the urine. The maximum value for plasma hemoglobin was 1.6 gm per 100 cc of plasma.

transfer, in one or another form, of fetal red blood cells into the maternal circulation Javert¹⁴ suggested that fetal red blood cells may enter the maternal circulation via placental thrombi in which he claims to have observed fetal red blood cells. This view could not be confirmed by Potter¹⁵ in a study of 60 placentae which had thrombus-like lesions. Burnham¹⁶ claimed that lack of or improper utilization of vitamin C produces placental lesions which would permit leakage of fetal red blood cells. Because of lack of evidence this view is generally not accepted.

In the first studies which demonstrated the role of the Rh factor in the pathogenesis of erythroblastosis fetalis, no attempt was made to describe the mechanism by which the fetal red blood cells, a large formed element, traverse the placenta. In the interval of 1941-1943, a concept was gradually developed which seemed to be compatible with the clinical and serologic findings.¹⁷

It is assumed that in every normal pregnancy minute quantities of fetal red blood cells, in one form or another, find their way into the maternal circulation in sufficient quantity to induce isoimmunization. According to this view, it is not necessary to assume the existence of gross placental lesions, which would have to recur with each successive pregnancy in which the fetus is Rh+. Another consideration is the fact discussed below, that only minute quantities of blood may suffice to immunize. The existence of gross placental lesions can also be excluded since the course of the pregnancy and the delivery in the vast majority of immunized mothers is entirely uneventful. Toxic symptoms are apt to occur only in some of the much smaller group of mothers of infants suffering from fetal hydrops and it is probable that these symptoms in the mother cannot be attributed to the effects of gross leakage.

From an immunologic viewpoint, it is safe to assume that minute quantities of fetal blood may suffice to induce isoimmunization. There are numerous examples in serologic literature to demonstrate that very small doses of soluble proteins, toxins, suspensions of bacteria or red blood cells administered to the experimental animal will result in antibody production. Perhaps the most outstanding example is sensitization of the guinea pig to anaphylaxis by the injection of, e.g., 10^{-6} cc. of horse serum (ca. 7×10^{-8} grams of protein).

In order to accumulate additional evidence with red blood cells as an antigen, the author injected a series of rabbits daily with 2 cc. of a 1:5000 suspension of citrated human blood. After seven injections there was a slight to moderate increase in the activity of the sera for human blood. The antibody response was more striking after a second series of injections (table 2).

It is of interest that one of the animals was comparatively resistant to the injections and that one of the remaining five animals produced anti-M agglutinins as well as species-specific antibodies. Measured in terms of sediment, the total volumes employed for the seven and fourteen injections were respectively, 0.0014 and 0.0028 cc. The corresponding values for an adult of 120 lbs (60 Kg) are 0.0336 and 0.0672 cc. respectively.

It is true that the above-mentioned experiment dealt with heteroimmunization and it seems desirable to determine whether or not the same principle applies also to isoimmunization of rabbits with minute quantities of rabbit blood of varying

antigenic constitution. However, there is already indirect evidence obtained from recent experiments on isoimmunization of Rh— donors with small quantities of Rh+ blood. This applies especially for the increase of antibodies already formed. From a practical viewpoint, one must consider that these experiments cannot simulate the conditions existing in pregnancy which are most favorable for antibody production, i.e., slow administration of the antigen over a long period. Certainly these conditions cannot be satisfied in either abortions, ectopic pregnancies, nor in the process of parturition.

By and large the effects of isoimmunization by the Rh factor are exerted on the fully, or almost fully developed fetus, or the newborn infant. Intra-uterine fetal death in the seventh or eighth month is never observed in the first born unless the mother has been immunized by previous transfusions of Rh+ blood. With increasing degrees of isoimmunization, fetal death may occur but scarcely before the sixth or seventh month. Remarkably enough, the presence of potent antibodies residual from the preceding pregnancy does not interfere with the process of fertilization, implantation, nor with the subsequent development and growth of the fertilized

TABLE 2 *—*Immunization of Rabbits with Minute Quantities of Human Blood (Group O)*

Time of Test	Agglutination Titers of Five Immunized Rabbit Bloods Tested with Blood Group O				
	1	2	3	4	5
Before injections	5	10	5	5	5
After 7 injections	15	100	25	25	10
After 14 injections	100	300	25	600	100

* After Levine¹⁷

ovum, even though red blood cells are already in the process of formation in the fourth week.²⁰ The Rh factor has been demonstrated in the blood of a 48 mm fetus by Stratton,²¹ and a 17 cm fetus by Bornstein.²² Diamond²³ demonstrated the Rh factor in the blood of three fetuses of 3 month development while Potter¹⁵ found the factor present in fifteen out of seventeen fetuses weighing between 8 and 200 grams. There is reason to suspect that the more fundamental property of antigenicity and capacity to unite with antibodies may be inherent in the earlier fetus or even in the embryologic forerunners of red blood cells.

Although immunized Rh— mothers have a somewhat higher incidence of abortions and miscarriages,²⁻²⁴ there is little or no statistical proof to indicate that early fetal death is brought about by the action of passively transferred maternal antibodies. While metabolites are transferred early in the course of development, there is no proof that the early fetus receives maternal antibodies. Certainly, the fetus does not require antibodies at this early stage of its development. In any event, this subject and its possible relationship to early fetal death merits further investigation. Whether or not an early abortion followed by a curettage results in the transfer of fetal blood into the maternal circulation with subsequent isoimmunization¹⁵ will be referred to below.

According to the author's concept, isoimmunization by the Rh factor does not

begin until after midpregnancy when certain structural changes occur which are favorable for the transfer into maternal sinuses of minute amounts of one form or another of fetal red blood cells.¹⁷ As the placenta grows the blood vessels in the villi, at first centrally located, become larger and come to lie adjacent to the maternal sinuses. During this period the Langhans cells degenerate and only a thin membrane and one layer of syncytial cells separate the fetal and maternal circulations. The gradual thinning of the barrier is readily demonstrated in a comparative study of histologic sections of normal placentae of varying periods of development. The retention of Langhans cells in the placentae of erythroblastotic infants does not invalidate the view presented since these changes may be considered as secondary responses to the hemolytic process.

At the same time there is an ever-increasing surface area of fetal villi in contact with maternal sinuses. It has been calculated by Dodds²⁵ and Dees-Mattingly²⁴ that in the term placenta there are from 70-120 square feet of fetal villi exposed to maternal sinuses and the total length of these villi, if laid end to end, would measure 11 4 miles. Furthermore, one fourth or more of the fetal blood is outside of the fetus and in close contact with the maternal circulation. It is known that the circulation in the maternal sinuses is very sluggish and that the pressure is greater in the fetal circulation. Accordingly, there is ample opportunity even under physiologic conditions for the escape into the maternal sinuses of a minute number of red blood cells in one or another form. One may well speculate that the pressure in the fetal villi is not constant, and may be increased as a result of fetal movements which generally become active in the fifth month.

The mechanism of isoimmunization described is compatible with the clinical observation that once an Rh- mother delivers an erythroblastotic infant, the condition is apt to recur in all succeeding pregnancies in which the fetus is Rh+. Apparently, the isoimmunization is renewed even if subsequent pregnancies are spaced at intervals which are sufficiently long for the complete disappearance of antibodies, residual from the preceding pregnancy. Thus, the specific form of the anamnestic reaction is called into play in each successive pregnancy, and the determining factor is the presence of Rh+ fetal red blood cells in the maternal circulation during the course of the pregnancy.

Transplacental isoimmunization by the Rh factor depends on (1), a combination of an Rh- mother and Rh+ fetus and (2), genetic capacity to respond to the antigenic stimulus. It is assumed that the mother whose first Rh+ infant is affected produces antibodies with greater ease than the mother who has several normal Rh+ infants prior to the first affected infant. These two facts serve to determine the comparatively low incidence of erythroblastosis in spite of the fact that there are 13 per cent incompatible matings ($85 \text{ per cent} \times 15 \text{ per cent} = 13 \text{ per cent}$). More than 50 per cent of these Rh+ fathers (about 58 per cent) are heterozygous and half of their offspring will be Rh-, like the mother. Another factor tending to reduce the incidence of erythroblastosis fetalis is the current tendency to small families. It is probable that every Rh- mother would produce an erythroblastotic infant provided that there were a sufficient number of pregnancies.

The same genetic factors determining the capacity to produce antibodies are

also operative in isoimmunization of voluntary donors by administration of Rh+ blood. Thus, Diamond and Wiener report successful isoimmunization in somewhat less than 50 per cent of the Rh- donors. Of 200 Rh- random individuals who were transfused indiscriminately, about 46 per cent produced antibodies for Rh. It is most significant that the antigenic response was independent of the number of transfusions, but determined rather by certain genetic properties. In contrast to the patient reported by Dacie and Mollison²⁸ who produced antibodies soon after the first transfusion is an Rh- patient studied by Levine who produced antibodies after a series of numerous transfusions.²⁹

As pointed out by Levine, the occurrence of erythroblastosis fetalis in the first born with or without previous transfusions has considerable bearing on the mechanisms of transplacental isoimmunization. In both groups of cases, there is a selection of those Rh- women who produce antibodies readily, but of the two, the nontransfused group is obviously the more sensitive to the administration of Rh+ blood. The objection has been raised that many of these women had one or more abortions, probably premarital, which are not obvious from the usual history. This raises the question whether or not fetal red blood cells may be carried over into the maternal circulation as a result of either a spontaneous abortion or the subsequent curettage. However, this is not likely, particularly if there is considerable uterine bleeding which would tend to carry with it the fetal blood. In any event, an early pregnancy cannot supply the conditions favorable for isoimmunization, i.e., slow administration of the antigen over a long period. In a number of cases studied by the writer a history of abortion was denied. A more important consideration is the likelihood that many of these women had previously received an intramuscular injection of presumably Rh+ blood.³¹ In the pre-vitamin K days, the intramuscular injection of blood was a common practice and more recently such histories were obtained, particularly if the indication was prophylaxis for either measles or poliomyelitis. Under such conditions the erythroblastosis fetalis in the first born is classified under the "transfused" group.

Erythroblastosis fetalis in the first born is a more common event in the transfused group and in many of these there is a long interval between the last transfusion and the first pregnancy. It is not likely that the antibodies produced as a result of one or more transfusions will be demonstrable for more than several years, but certainly not for five years, at least in the vast majority of the cases. Accordingly, it may be assumed that in many of these cases, no antibodies are present when the first pregnancy is started. The subsequent appearance of antibodies during the course of the pregnancy provides proof that fetal Rh+ blood cells must have passed the placental barrier in sufficient quantity to exert its antigenic effect.

The following case of erythroblastosis fetalis in the first born referred by Dr Regina Beck of Richmond, Virginia is cited because antibodies, which were not demonstrable either early in the course of the pregnancy, i.e., the twelfth week or in the thirty-third week, were found in a specimen drawn in the thirty-eighth week (titer = 1:64). This Rh- patient was transfused six times in 1941 for gastroenteritis, five years prior to her first pregnancy. It is significant that in the specimen drawn seven weeks prior to the expected date of confinement (July 17, 1947)

the serum failed to sensitize Rh+ cells so that the precipitin reaction of Coombs, Mourant, and Race³² was completely negative. In view of her history, the patient's serum was titrated and as was to be expected, the existence of a prozone in the lower dilutions was excluded.³³ Assuming a two or three months' preparatory period, one may speculate that fetal red cells began their passage between the twenty-sixth and thirtieth week of the pregnancy. Since there were six transfusions, of which probably five were with Rh+ blood, the patient must be considered as relatively resistant to the production of antibodies.

Curiously enough there are remarkably few cases in which there are sufficient data useful for this analysis. As a rule these patients do not submit to the test until late in the course of the pregnancy when antibodies are already demonstrable and their origin, whether residual or newly formed, cannot be determined. However, indirect evidence may be obtained in an analysis of the interval between the last transfusion and the first pregnancy with an Rh positive fetus. In a combined series of 52 cases of erythroblastosis fetalis in the first full term Rh+ infants, the average interval was six years and as mentioned above it is safe to assume that (1) the antibodies which may have been present earlier will have disappeared in the six years' interval and (2) that the appearance of antibodies responsible for erythroblastosis fetalis was the result of intra-uterine passage of fetal blood.*

Of the 52 cases, 10 had previous histories of abortions or ectopic pregnancies and 9 of the 10 required blood transfusions. The average interval between the transfusion and the first pregnancy resulting in an erythroblastotic infant was 3.7 years. The shorter interval does not indicate that the abortions resulted in isoimmunization. In women of child-bearing age, one cannot expect to find long intervals between pregnancies. Excluding this series, the interval in the remaining 42 cases between the transfusions and the first pregnancy was 6.4 years.

In 2 cases a history of intramuscular injection of blood could be elicited at intervals of eleven and seventeen years respectively prior to the delivery of the erythroblastotic infant in the first pregnancy. The indications for the administration of blood were prophylaxis against measles and poliomyelitis. Each of these 2 patients denied having previous pregnancies and/or abortions.

Finally, there is the group of twelve instances of erythroblastosis fetalis in the first born in which there is neither a history of transfusion or abortions. An additional 4 patients gave a history of early abortion. However, this can play no essential role in initiating transplacental isoimmunization which requires prolonged and slow administration of Rh positive fetal blood. It was in this group of cases that the suggestion was first made by Levine that these patients may have had intramuscular injections of blood many years previously. In the event that this antigenic stimulus can be excluded, these Rh- women can be considered as the group most susceptible to isoimmunization. Unfortunately there is as yet no known procedure which will differentiate this group from the group which is more resistant to isoimmunization.

Possibly fetal red blood cells escape into the maternal circulation in the course

*This includes a second series of cases to be published by Levine and Rosenfield.³⁴

of the second stage of labor when the placenta begins to separate * Perhaps this serves to explain the increase of antibody content occasionally observed in the postpartum period However, parturition by itself can play no essential role in the group of cases discussed above and by the same token its importance in the mechanism of isoimmunization in general can be excluded

As indicated above there is no final proof for the concept that fetal blood cells find their way into the maternal circulation in every normal pregnancy However, this view seems to be compatible with serologic, clinical, and pathologic features of erythroblastosis fetalis Most workers hesitate to accept the theory of transplacental isoimmunization probably because of the traditional concept that the placenta presents a barrier which is absolutely impermeable to formed elements It would indeed be quite unique if nature repeatedly provided an absolutely perfect organ which in the course of its short life of 40 weeks attains a surface area of 70-120 square feet required for the nourishment of the fetus This would be all the more remarkable because of the rapid proliferation of the trophoblast which is endowed with invasive properties similar to that of the malignant cell

A discussion of the mechanism of transplacental isoimmunization cannot be complete without reference to the passage of maternal antibodies into the fetal circulation Recent attempts to associate prolonged intra-uterine action on the part of blocking antibodies with hemolysis and rapid action of agglutinins only at delivery with severe jaundice and toxicity have been shown to be premature ³⁶ Although there are striking differences between agglutinins and blocking antibodies demonstrable in vitro, these differences lose their significance because in vivo both react with fetal blood suspended in a medium of plasma In any event, blocking antibodies in contrast to anti-Rh agglutinins are frequently demonstrable in the infant's circulation

The study of affected infants before and after a more or less complete replacement transfusion reveals the significant fact that appreciable quantities of blocking antibodies can still be demonstrated at the end of the replacement transfusion when the vast majority of the blood is not coated Presumably, large quantities of blocking antibodies are stored in the tissue spaces and hence, the continued blood destruction of any residual Rh+ fetal blood in the neonatal period Certainly, there seems to be little or no indication for the use of Rh+ blood in transfusing affected infants of Rh- mothers

With an antigenic stimulus acting over a period of several months in any one pregnancy and its renewal in the following pregnancies with Rh+ fetuses, it is not surprising that more than one variety of antibody is produced In a sense many Rh- women are subjected to hyperimmunization More recently, a third variety of antibody could be demonstrated in certain blocking sera which are characterized by a distinct prozone in the lower dilutions The antibody responsible for the prozone can be specifically absorbed after contact of the undiluted serum with Rh+ but not with Rh- blood (Levine and Wigod) †

*Should the Rh factor be found in syncytial cells, their liberation in the postpartum period might also serve to immunize

†Cf Hill and Haberman ³⁷

These findings raise the question as to the nature of the globulin antibody produced by the immunized mother. One may speculate that the antibodies produced represent an ever changing configuration of the immune globulin without losing its characteristic specificity. It is not excluded that at times an antibody may be produced which has little or no capacity to pass the placental barrier. Possibly this may serve to explain the rare instances of entirely normal or mildly affected Rh+ infants delivered by intensively immunized Rh- women whose previous pregnancies resulted in severely affected infants (Chown³⁵).

ADDENDUM

Claims were made recently that physiologic breaks in the villi could be demonstrated either by means of serial sections (Naeslund and Aren³⁹) or by the presence of nucleated red cells of the erythroblastic fetus in intervillous spaces (Kline⁴⁰). These observations require confirmation because of the inherent difficulties in providing histologic proof of physiologic breaks in the continuity of blood vessels of such delicate tissue as the placenta.

ERYTHROBLASTOSIS FETALIS IN NEGROID INFANTS

By A S WIENER, M D , AND I B WEALER, M D

THE INCIDENCE of erythroblastosis among Caucasoids, as given by different authors, varies from 1 in 400 to 1 in 150 births ^{1 2} Despite the tremendous increase in interest in the disease since Levine et al ³ and Burnham⁴ demonstrated the role of the Rh factor of Landsteiner and Wiener^{5 6} in its pathogenesis, no reports have come to our attention concerning the appearance of the disease in Negroid infants We have recently encountered 3 such cases having unusual features, and these are the subject of this report

CASE REPORTS

Case 1 The patient, a male infant, was born at the St John s Hospital on October 8, 1946 This was the mother s first pregnancy and the entire period of gestation was uncomplicated There was no history of luetic infection and the Wassermann reaction of her blood was negative Delivery was spontaneous, at term, and the infant cried immediately The only abnormality noted at the delivery was a yellow discoloration of the vernix and amniotic fluid, while the cord was normal The birth weight was 7 pounds, 8 ounces

The infant appeared to be normal until the second day of life when moderate icterus of the skin and sclerae was noted There was no enlargement of the liver or spleen and the baby appeared to be otherwise well On the following day, however, jaundice became more intense and the infant vomited its feedings Laboratory findings at this time were as follows Hemoglobin concentration of the blood, 13 grams per 100 cc , red blood count, 4.5 million per cu mm , white blood count 9,500 per cu mm There were 2 normoblasts per 100 white blood cells on the smear The stool was yellow green and gave a negative test for blood Bleeding, coagulation, and prothombin times were normal The infant s red blood cell fragility was normal Both the mother and the baby were found to be Rh positive *

The hemoglobin fell slowly for the next few days and on the sixth day of life was found to be 9.5 Gm per 100 cc with a red count of 3.95 million per cu mm One eosinophile and 2 normoblasts were seen on the smear at this time Because of the falling hemoglobin and red count, a transfusion of 50 cc of group B, Rh-positive blood was given On the day following the transfusion, the hemoglobin had risen to 11.5 grams per 100 cc with the red count 3.92 million per cu mm This rise was not maintained, however, and a second transfusion of group B, Rh-positive blood was given Twelve days later the blood count had again fallen and now showed a hemoglobin of only 7.6 grams per 100 cc and a red count of 2.67 million per cu mm

Because of the obscure etiology of the patient s anemia and the poor response to transfusion therapy, the case was referred to us for further study Results of grouping and Rh-Hr tests on the father, mother, and infant were as follows

Blood of	Group	M N Type*	Rh Hr Type†
Father	AB	N	Rh.
Mother	O	MN	Rh ₀
Infant	B	MN	Rh ₀

From the Transfusion Division of the Department of Laboratories, and the Department of Pediatrics of the Jewish Hospital of Brooklyn

* The types M N are not of clinical significance, but are included for the sake of completeness

† For heredity and nomenclature of the Rh-Hr types, see Wiener ^{7 8}

Titration of the alpha and beta antibodies in the mother's serum showed an anti-A titer of 15 units by the agglutination method and also 15 units by the conglutination method, the anti-B titer was 60 units by the agglutination method, by the conglutination method a titer of 600 units was obtained.* These results show that the patient's anemia and poor response to transfusion were due to sensitization of the mother (group O) to the infant's erythrocytes (group B). On our recommendation, two small transfusions of group O red cells (plasma free) were then administered, after which the infant made an uneventful recovery. When seen again in the clinic at the age of 7 weeks, the infant weighed 9 pounds, 5 ounces and had no jaundice. Blood count was not done.

Case 2 A Negress was referred to us with the following obstetrical history. Her first pregnancy in 1941 resulted in the birth of a normal male infant, who is living and well. The second pregnancy, in 1943, also gave rise to a normal male infant. Her third pregnancy terminated prematurely (8 months) with the birth of a male infant who became jaundiced at the age of 3 days. He was kept at the hospital for three weeks during which time the jaundice subsided. He was not transfused during his hospital stay and appeared well on arriving home. Shortly thereafter, however, he was seen to be pale. He was transfused immediately but lost weight, developed jaundice and died. The mother was now pregnant for the fourth time and the problem of the prognosis and treatment for the expected infant was presented to us. According to the mother, previous tests had shown her to be Rh negative and her husband Rh positive.

Results of grouping, Rh-Hr tests on the father, mother, and the two surviving sons were as follows:

Blood of	Group	M-N Type	Rh Hr Type
Father	B	M	Rh ₂
Mother	O	MN	Rh ₁ Rh ₂
1st son	B	M	Rh ₁ Rh ₂
2nd son	O	M	Rh ₁ rh

These results show that the Rh-Hr types had nothing to do with the problem and that the previous report of the mother's Rh type was in error. Titration of the alpha and beta antibodies in the mother's serum showed an anti-A titer of 25 units by the agglutination method and a titer of 20 units by the conglutination method. The anti-B titers on the other hand, were 100 units by the agglutination method and 500 units by the conglutination method.

These findings support the diagnosis of erythroblastosis as the cause of death of the third infant, but with the B factor and not the Rh factor as the sensitizing agent. It must have been the first child who sensitized the mother, while the second escaped because it belonged to group O. The prognosis for the expected infant now depends upon its blood group. If it belongs to group O (50 per cent chance) it will not be erythroblastotic. If, however, it belongs to group B it will almost certainly have the disease. In such cases, the prophylactic injection of soluble A and B group substances into the infant by way of the umbilical vessels at the time of birth may serve to ameliorate the disease.¹⁰

Case 3 The patient was a second child, female, born at term after a short labor. Pregnancy was uncomplicated and the Wassermann and Kline reactions of the mother's blood were negative. The baby weighed 9 pounds, 9 ounces at birth and was seen to be lethargic, pale, and appeared to have difficulty in breathing. A bradycardia of 110 beats per minute was present. There was no apparent jaundice, nor was the amniotic fluid or vernix discolored. A blood count done shortly after birth showed a hemoglobin concentration of only 7.7 grams per 100 cc, with a red cell count of 3.2 million per cu. mm., a white cell count of 86,000 per cu. mm., and 82 nucleated red blood cells per 100 white cells on the smear. The mother's blood was found to be A₁MN Rh₁rh, and the baby's blood A₁MRh₁rh. There was therefore no known factor present in the infant's erythrocytes that was lacking from the mother's and no sensitization was possible.

* By the method of titration used, the average normal titer with the agglutination technique is approximately 40 units. In nonsensitized individuals, the titer by the conglutination technique is lower, or at least not higher, than that by the agglutination technique.^{9, 11}

to the A, B, or Rh-Hr factors. A 'coating' test (conglutination technic)¹¹ done on the baby's cells was negative, and tests done on the mother's serum for the presence of abnormal iso antibodies were negative.

Transfusion to combat the anemia was indicated and the type of blood to use presented a problem. In view of the possibility that the case might be one of isosensitization against a blood factor as yet undiscussed, it was decided to use the mother's washed red cells, because her erythrocytes could not contain the hypothetical immunizing factor. The child was therefore transfused with the washed red cells obtained from 100 cc. of the mother's blood resuspended in saline.¹² On the day following transfusion the hemoglobin had risen to 15 grams per 100 cc. Two days after birth jaundice was found to be present, and the hemoglobin had fallen to 11 grams per 100 cc. A blood smear at this time showed that there were 276 nucleated red blood cells per 100 white cells. Periorbital edema appeared and the transfusion of mother's blood, using the washed red cells obtained from 100 cc. of blood, was repeated. Response to this transfusion was good in that the hemoglobin now rose to 15.5 grams per 100 cc. and the red count to 5.67 million per cu. mm. However, there still were 216 nucleated red blood cells per 100 white cells on the smear. Within two days the nucleated red cell count had fallen to 12 per 100 white blood cells and five days following the second transfusion nucleated red cells were no longer present. Fragility tests done on the twenty-first hospital day were within normal limits. Numerous sickling preparations were negative, immediately and after twenty-four hours. Cultures of the nose and throat, stool, and blood failed to reveal any pathogenic organisms. X-ray of the skull showed no abnormalities. The child's clinical course was uneventful. She was discharged at the end of the fourth week weighing 5 pounds 9 ounces, with a hemoglobin of 10 grams per 100 cc. and a red cell count of 2.85 million per cu. mm. She had no jaundice at the time of discharge. When seen in the out-patient department, four weeks after discharge, she weighed 8 pounds, 1 ounce. Her hemoglobin had fallen to 9.1 grams per 100 cc. and her red count was 2.9 million per cu. mm., but otherwise she seemed well.

COMMENT

If the Rh factor played the same role in all races as it does in the Caucasian, one would expect the incidence of erythroblastosis in the various races to correspond with the frequency of the Rh-negative type. This expectation has apparently been fulfilled in the Mongolian race, since erythroblastosis is extremely rare amongst these peoples.¹³ Among Negroids, with a frequency of Rh-negative individuals variously reported as between 5 and 10 per cent, one might similarly expect an incidence of erythroblastosis from one third to two thirds as high as in Caucasians. As we have already mentioned, however, erythroblastosis appears to be rare among Negroes, indicating that considerations other than the Rh type play an important role in the pathogenesis of the disease. It is particularly remarkable that in the 3 cases reported here with the clinical picture of erythroblastosis, none showed evidence of Rh sensitization. Somewhat similar observations have been made by Zuelzer.¹⁴

Recent observations indicate that the efficiency of sensitization in Rh-negative individuals depends in part upon the amount of Rh-positive blood inoculated into the body. For example, Rh-negative women, who at the first pregnancy have had stillbirths due to Rh sensitization, almost always show a history of having received a transfusion or intramuscular injection of blood some time in the past.¹⁵ Furthermore, experiments done to produce Rh testing sera in male donors have shown that the great majority of Rh-negative individuals are readily sensitized by properly spaced injections of as little as 2 cc. of Rh-positive blood.¹⁶ On the other hand, the observation that isosensitization by pregnancy appears to occur in only 1 out of 25 to 50 Rh-negative women, may be explained by the fact that during pregnancy or parturition only minute quantities of Rh-positive blood enter the maternal

circulation, and at intervals not necessarily optimal for the stimulation of antibody production. Another factor is the constitutional ability or lack of ability to be sensitized.¹⁷ The situation is analogous to that existing in allergic diseases¹⁸ or infections. An overwhelming dose of antigen or pathogenic organism will sensitize or infect all human beings, a minute dose will affect only the most susceptible. Accordingly, if one assumes that in Negroid races the placenta offers a better barrier to the passage of materials from the fetus to the mother, this would account for the rarity of erythroblastosis among these peoples. An alternative possibility is that among Negroids the frequency of individuals easy to sensitize is very low.

Past investigations have furthermore demonstrated that injections of soluble A and B substances in small amounts of secretions such as saliva may give rise to sensitization to these factors, while corresponding doses of red cells containing these substances are inadequate to sensitize.¹⁹ Therefore, passage of soluble materials from fetus to mother may give rise to A and B sensitization under conditions which would be inadequate to cause Rh sensitization, because comparable small quantities of red cells would not be antigenic. It is therefore significant that 2 of our 3 cases can be explained on the basis of A and B sensitization. With regard to the third case, no evidence of isosensitization could be obtained, and if erythroblastosis is strictly defined as comprising those conditions in the newborn caused by isosensitization of the mother by an antigen in the fetal blood, then this case does not satisfy the conditions, according to our findings. However, there are a host of clinical conditions producing jaundice, anemia, hepato-splenomegaly and erythroblastemia in the newborn. Cases such as this, in which no satisfactory conclusion could be drawn demonstrate that there is still much to be learned in this most interesting field.

SUMMARY

Three cases of Negroid infants with clinical signs and symptoms resembling erythroblastosis fetalis were presented. In none of the cases was there any evidence of Rh sensitization. Two of the cases were apparently due to sensitization of the mother to the B agglutinin, in the third case no serologic incompatibility could be demonstrated. The possible significance of these observations was discussed.

AUTOHEMAGGLUTININS AND HEMOLYSINS WITH HEMOGLOBINURIA AND ACUTE HEMOLYTIC ANEMIA, IN AN ILLNESS RESEMBLING INFECTIOUS MONONUCLEOSIS*

By LAURENCE B ELLIS, M D , OSCAR J WOLLENMAN, M D ,
AND RICHARD P STETSON, M D

ACUTE acquired hemolytic anemia is uncommon, but dramatic in its clinical picture and often disastrous in its outcome. In 1940, Dameshek and Schwartz¹ assembled about 100 cases reported in the literature since 1907, in which no definite etiology was evident. In addition, as cited by these authors, cases have been reported in which the anemia developed in association with definite or probable etiologic factors. These include malaria, infections with streptococci, staphylococci and certain anaerobic organisms, as well as tuberculosis, syphilis and anchylostomiasis, also pregnancy, lymphoma, leukemia, carcinomatosis, and, finally, various drugs, especially the sulfonamides but also arsenical preparations, phenylhydrazine and acetanilide. Hemolytic anemia has also been reported in association with atypical pneumonia of unknown etiology^{2, 3} and its occurrence in patients who have received sulfonamides is well established.⁴ Studies of these cases in regard to the presence of hemagglutinins and hemolysins have given varied results.

The case of acute hemolytic anemia with hemoglobinuria which is herewith reported is of interest because of the association of the unusual combination of auto-hemagglutinins and hemolysins occurring in the presence of morphologic changes in the white blood cells and heterophile agglutinins in the blood serum consistent with infectious mononucleosis, together with a positive Donath-Landsteiner reaction and the absence of evidence of syphilis.

The patient was observed during the acute stage of his illness by two of the authors (O J W and L B E) and more than two years later by the third author (R P S).

REPORT OF CASE

Present Illness H J H, a 21 year old single white male was admitted to an Army hospital in the European Theater on January 9, 1945, with a three day history of bloody urine. Two weeks prior to admission he had developed an upper respiratory tract infection with a nonproductive hacking cough, headache, moderate nausea and anorexia. There was no vomiting until the day before admission when he had vomited once without hematemesis. On the evening of January 6, he first noted dark bloody urine, unaccompanied by urgency, frequency, dysuria or nocturia. The dark urine continued for the three days prior to admission. During this interval he developed a steady aching pain in the epigastrium and in the lumbar region. Generalized weakness and dyspnea on exertion became moderately distressing, but he continued on duty until admission. At no time did he experience chills, fever, icterus, or symptoms referable to the lower intestinal tract. His weight had decreased from his usual 128 pounds to 105 pounds on admission.

From the Thorndike Memorial Laboratory and the Second and Fourth Medical Services (Harvard) of the Boston City Hospital, and the Department of Medicine, Harvard Medical School.

* This patient was observed from January to March, 1945, in an Army Hospital in the European Theater of Operations and subsequently in 1947 in a Veterans Administration Hospital.

Past History In 1937 he had an uncomplicated appendectomy, in 1942, a hemorrhoidectomy. On July 21, 1944 he was admitted to an Army General Hospital with lymphadenitis of the right arm and was discharged well on August 10. On August 24, 1944 he developed impetigo and was treated with ammoniated mercury and ultra violet light until September 16, 1944 when he was discharged as well. From September until the present illness, approximately four months later, he enjoyed good health. In November, 1944 his attention had first been called to asymptomatic enlargement of his finger tips which had not changed since, to his knowledge.

During the few days immediately preceding entry, he had developed a generalized pruritic skin lesion which, on admission, proved to be scabies. During his three years of army service he had never had tropical service, and he had not been exposed to any known hemolytic agents. He had received no sulfonamide drugs for at least six months prior to his illness. His diet had been adequate. Alcohol had not been used habitually nor in excess immediately prior to the present illness. There was no history of venereal disease. He had never experienced an illness similar to the present malady, nor had he ever been seriously ill.

Family History No similar illness was known. The familial history was noncontributory.

Physical Examination Temperature 99.4 F, pulse 110, respiration 20, blood pressure 120 mm of mercury systolic and 70 mm diastolic. He was ambulatory and complained chiefly of weakness. He did not appear acutely ill but was pale and slightly icteric. Scabetic furrows and scratches were present over the trunk and extremities. (Subsequent treatment for scabies led to rapid clearing.) The mucous membranes were moderately pale but presented no evidence of hemorrhage or ulceration. There was a nontender left infra-auricular lymph node approximately 1 cm in diameter. No other lymphadenopathy was detected. The thyroid was not enlarged. The chest was symmetrical and the examination of the lungs was normal. The heart was not enlarged. There was a strong apical impulse and a blowing apical systolic murmur was heard on auscultation. The abdomen was scaphoid with an indefinite epigastric tenderness. The liver and spleen were palpable only on inspiration and were tender. The kidneys could be palpated but were not enlarged or tender. The genitalia were normal. The fingers presented a striking terminal enlargement characteristic of clubbing, the nails appeared otherwise normal. The toes did not show similar changes. The extremities were not cold or sweaty. Examination of the long bones, skull, the muscular and the neurologic systems was not remarkable. There was no demonstrable edema or evidence of dehydration.

LABORATORY DATA

Methods Employed References are given below to the technical methods employed in the laboratory examinations.

Urine Examination hemosiderin (Rouss technique⁵), porphyrins⁵, alkaptone bodies⁵, bile (Rosenbach's modification of Gmelin's test⁶), urobilinogen (Wallace and Diamond modification of Ehrlich aldehyde test⁶), hemoglobin in plasma and urine⁷, indican (Obermayer's test⁶).

Blood Examination hemoglobin (alkaline hematin method using a Coleman spectrophotometer), red cell fragility⁸, erythrocyte count (Hayem's solution), platelet count⁸, bleeding time (Duke's method⁸), clotting time⁸, hematocrit and sedimentation rate (Wintrobe method⁸), test for sickle cell trait⁸.

Serologic Examination heterophile agglutination, presumptive test (Davidsohn technique^{10, 11}), Donath-Landsteiner⁹, hemolysis test with acidified serum⁷, cold hemagglutinins¹².

Other methods employed were either too well known to require comment or are described in the text.

Hematologic data during this hospitalization are given in table 1 and figure 1.

RESULTS

1 *Anemia* The anemia was obviously hemolytic in type as evidenced by extreme hemoglobinuria, and became profound on the day following admission, the hemoglobin dropping from 12.2 grams per cent at 10:00 A.M. to 5.9 grams per cent by 3:00 P.M. of the same day. At this time blood platelets were 232,000, bleeding time one minute, clotting time five and one-half minutes (capillary tube), and clot re-

* 1.64 Patient's cells

traction normal The osmotic fragility test of the patient's red blood cells was identical with the control on the second hospital day, on three subsequent occasions within the next month, and two years later, in 1947 During the first two days difficulty was encountered in performing erythrocyte counts due to clumping of the cells in the pipet at the room temperature of approximately 20 degrees Cent

FIG 1

grade Subsequently warm saline solution was employed as a diluent and counts were then satisfactorily made

The course of the anemia is shown in figure 1 Therapy consisted of transfusions of whole blood and concentrated red cells as described below, iron therapy and a high caloric, high vitamin diet

2. *Morphology of the Blood* Examination of the morphology of the erythrocytes was not striking The anemia was essentially normocytic and normochromic and the red blood cells appeared morphologically normal No nucleated red cells were

observed. The reticulocytes rose during the first and second week as shown in figure 1. There was an initial leukocytosis on January 10 of 24,300, with a differential of segmented polynuclear cells 32 per cent, eosinophiles 2 per cent, lymphocytes 64 per cent, monocytes 2 per cent. The lymphocytes were typical of the cells seen in infectious mononucleosis; the majority conformed to Downey's Class I¹³, a small percentage were Class II and III. The leukocyte count did not exceed 10,000 per cubic millimeter after the second week and the relative lymphocytosis with the atypical lymphocytes gradually disappeared.

3 *Hemagglutinins and Hemolysins* On admission hemagglutinins in the patient's serum with red cells of blood group O were demonstrated in a dilution of 1:256 at 4-6 degrees Centigrade. Clumping also occurred at 10 and 20 C and persisted when the test was carried out in the incubator at 37 C. When preparations which previously had been chilled at 4-6 C were subjected to a temperature of 37.5 C for one hour the clumping persisted and hemolysis occurred. There was no hemolysis at 4-6 C. After subjecting the patient's serum to a temperature of 56 C for inactivation of serum complement hemolysis was not observed but agglutination reactions were

TABLE 2 — *Presumptive Donath-Landsteiner Test**

Temperature Conditions	Plasma Hemoglobin of Defibrinated Blood	
	Patient	Control
	mg per 100 cc	mg per 100 cc

1 hr at 37.5 C	90	21
20 min at 4-6 C, then 1 hr at 37.5 C	370	21

* Two cc samples of defibrinated blood from the patient and a normal control were treated as indicated.

maintained. The hemagglutination against red cells of blood group O dropped to 1:64 by January 14, where it remained throughout this hospital admission.

The presumptive (table 2) and more complete Donath-Landsteiner tests (table 3) were strongly positive on admission, guinea pig serum was not available for addition as a source of complement to the heat inactivated serum. Donath-Landsteiner tests were repeated seven weeks later, with the same positive result. The Kahn and Wassermann tests were negative on four occasions during this month, and again in December, 1945 and January, 1947, and there was no history or physical sign of syphilis.

The relationship between chilling of the patient and the development of increased hemoglobinemia and hemoglobinuria was explored but unfortunately without conclusive results. During his hospitalization the patient was exposed to the usual environment of a drafty Nissen hut ward heated by coke stoves in England in the winter. During the first day of his stay he was a 'bed patient,' but was rather recalcitrant and difficult to keep in bed. The opportunity for chilling undoubtedly existed. No hemoglobinuria was present after the fourth hospital day. Obvious hemoglobinemia was observed on admission and on several occasions during the

first four days of hospitalization. Subsequent observations of the plasma showed moderate hemoglobinemia, above the level of controls, until January 16. Quantitative results are not reported because of difficulty in preparing a proper benzidine reagent.⁷ An attempt was made to test the effect of chilling by placing the patient's arm in ice water on March 13. The experiment had to be terminated in fifteen min

TABLE 3 — *Donath-Landsteiner Test*

utes because the patient fainted. No hemoglobinuria developed and the changes in the red blood cell count and level of free plasma hemoglobin were equivocal (table 4). The high levels for plasma hemoglobin in all control samples were considered to result from the benzidine reagent as mentioned above, precautions were taken to prevent hemolysis in obtaining the blood samples.

As shown in table 5, the hemolysin was absorbed from the patient's serum at 4-6 C by normal group A red blood corpuscles and was not removed by three washings

in saline at room temperature. The hemolysin was active only in the presence of complement since inactivation of normal serum at 56 C prevented the hemolysis which occurred with fresh unheated serum.

4 *Heterophile Antibody* On admission, the heterophile agglutination was positive in a dilution of 1:1024, and remained at that level 10 days after admission on January 19. On February 10 it had fallen to 1:128, at which level it persisted throughout his stay in this hospital. Unfortunately, it was not possible to absorb the serum with guinea pig kidney or ox cells to determine the variety of heterophile antibody.¹¹

TABLE 5 — *Absorption of hemolysin (March 12, 1945)*

Tube number	RBC—5% suspension in saline 0.5 cc	Serum—fresh 0.5 cc	Serum—heated 5 min 56C 0.5 cc	Treatment of mixtures	Hemolysis

5	C fresh	P ₂		Chilled 20 min at 4-6 C, incubated 1 hr at 37.5 C	0
6	C ₂ (Washed 3 times in saline)		C	Incubated 1 hr at 37.5 C	0

*P = Patient, C = Normal Control, red cells washed three times in physiological saline at room temperature. Both blood samples were Group A.

5 *Blood Grouping and Transfusion Therapy* Upon admission blood grouping with rabbit immune sera and washed red cells of the patient at 37 C indicated that the patient belonged to blood group 'O'. The same group was recorded on his Army Identification tag. Later, it was demonstrated both by us and the North East London Blood Supply Depot that the patient was, in reality, blood group A, as demonstrated by high titer grouping serums. No studies were made to determine the possible subgroups A₁ and A₂.

In spite of hemagglutination demonstrated at room temperature and at 4-6 C, it was evident that transfusions were necessary to combat the rapid fall of the hemoglobin. Since the initial blood group was considered to be group O, 1500 cc of group O blood, warmed to body temperature, was given on the evening of

UNUSUAL PICTURE IN POSSIBLE INFECTIOUS MONONUCLEOSIS

January 10 There was no reaction The Rh blood group could not be determined at this time since anti-Rh serum was not available

Transfusions were continued and a total of 7500 cubic centimeters of blood was given between January 10 and 21 * The patient occasionally complained of pain in the right and left upper quadrants following transfusion but no evidence of increased hemolysis could be demonstrated as having occurred Only group O blood without Rh determination had been given up until January 24 At that time anti Rh serum became available and a mixture of Rh negative and positive cells was demonstrated in the patient's blood Rather than speculate which were the undetermined Rh blood which had been given, concentrated Rh negative group A cells from 2000 cc of whole blood were suspended in physiologic salt solution and administered at room temperature on January 24 A transient slight pyrogenic reaction followed No further transfusions were given prior to evacuation to the United States

6 *Urinary Findings* The admission urine specimen, January 9, was port wine in color, showed 3 plus albumin, a 4 plus reaction for hemoglobin and a 1 plus bile test Tests for sugar, acetone, porphyrin, indican, alkapton and hemosiderin were negative Urobilinogen and urobilin were not determined on this specimen Numerous granular casts were present in the centrifuged specimens but no white blood cells, red blood cells or blood cell casts On the second hospital day the urine was dark but not red It contained a 2 plus albumin, 2 plus bile, but the test for hemoglobin was negative and the sediment was negative Spectroscopic examination of the specimen by the North East London Blood Supply Depot, Luton, England, showed an increase in urobilinogen, urobilin and bile but no evidence of porphyrins On the fourth hospital day the morning specimen showed a 4 plus reaction to benzidine, an afternoon specimen was free of hemoglobin and no specimen there after contained either hemoglobin or bile Urine urobilinogen was positive in 1:40 dilution on the fifth and eighth hospital days and remained positive in 1:80 to 1:160 dilution until January 24 when it became entirely normal Concentration tests and fractional phenosulphonphthalein excretion tests were normal

7 *Miscellaneous Tests* In addition to the laboratory examinations already discussed, numerous other tests were carried out and are shown in table 1 All, including chest roentgenograms on admission, were normal or unrevealing as to the nature of the hemolytic process

Course in Hospital During the first two weeks the patient was critically ill, but throughout this period, as well as later, was active and loathe to stay in bed By January 22, the anemia had ceased to progress and from then on steady improvement occurred A peak reticulocytosis of 9.8 per cent was found on February 10 During the period of marked anemia the patient exhibited a low-grade fever, reaching 101 F on two occasions As the red blood cell level was restored, the temperature returned to normal and after February 8 never exceeded 99 Fluid intake and output were satisfactory The patient gained 5 pounds during the two month hospitalization

* All blood was generously supplied by the N E London Blood Supply Depot, Luton, England

Subsequent Course and Present Condition The patient was evacuated to a hospital in the United States as an ambulatory patient on March 12, 1945. There, in April, the heterophile test was still positive (titer unavailable) and serum phosphorus, calcium and alkaline phosphatase determinations were normal, as was an electrocardiogram. Roentgenograms showed widespread slight osteoporosis of the tibiae, fibulae, lumbar vertebrae and skull. Biopsy of a lymph node from the right inguinal region was reported as showing subacute inflammation, not inconsistent with infectious mononucleosis. He was transferred to another hospital in December, 1945 when he developed a fissure of the rectum and hemorrhoids and was operated upon uneventfully. At this time, the sedimentation rate was 32 millimeters per hour, whole blood chlorides 479 milligrams per cent, CO₂ combining power 61 volumes per cent, serum phosphorus 3.8 milligrams per cent, serum calcium 11.3 milligrams per cent, and urea clearance test was 72 per cent of normal. Sternal puncture was negative and a modified Donath-Landsteiner test was now negative. During this entire period he remained weak, underweight, developed pains in his legs of increasing severity, clubbing of the toes was observed at that time with an apparent increase in the clubbing of the fingers. He was discharged from the Army in January, 1946.

On January 21, 1947, he entered a Veterans Administration Hospital for further study, where he remained until March 7. His complaints were persistent aching in the legs, a pressure sense in the rectum with frequent mucoid defecations, listlessness, nervousness and chronic fatigue. On physical examination he appeared somewhat agitated, there was audible hyperperistalsis and tenderness upon palpation of the rectum and prostate, clubbing of the fingers and toes, cold, clammy hands and feet, and marked adenopathy in the inguinal, femoral and posterior cervical regions.

Extensive laboratory studies were made at this time.* They are shown in table 1. In essence, all hematologic studies were then within normal limits. Six serologic tests for syphilis were carried out and were negative (Kahn, Kolmer, Kline, Eagle, Hinton, Mazzini). Stool examination showed mucus but no blood, parasites or ova. Sigmoidoscopy was normal.

Roentgenograms of the chest including bronchograms were normal. The hands and feet and long bones showed clubbing of the terminal phalanges of all fingers and toes, and there was expansion of the carpal and metacarpal bones with coarseness and trabeculations and thickening of the cortex. The skull had a somewhat granular appearance. A barium enema revealed a spastic colon.

DISCUSSION

Did this patient have infectious mononucleosis? The heterophile antibody decreased coincident with the decrease in serum hemagglutinins but at all times it was positive in much higher dilution than was the hemagglutinin. Belk,¹⁴ in studying a patient convalescent from infectious mononucleosis, found not only heterophile agglutinins and hemolysins against sheep, horse, rabbit and pig cells, but also autoagglutinins which were active below 10 Centigrade, but not at 37. He suggested that a nonspecific stimulus in this disease might result in a widespread production of antibodies. In a study of cold agglutinins, Favour¹⁵ found them present in four of ten cases of infectious mononucleosis, with a maximum titer of 1:180. Springyarn et al.¹⁶ have demonstrated them in seven cases of this disease. In their search for cold hemagglutinins in various disease states, Finland and his associates¹² found none in the three cases of infectious mononucleosis which they investigated. Davidsohn¹⁷ found the titer of isoagglutinins normal in 44 cases of infectious mononucleosis.

The morphologic white blood cell picture of hemolytic anemia is usually described as an absolute and relative polymorphonuclear leukocytosis. An absolute and relative lymphocytosis, as seen in our patient, is unusual, and the presence of atypical lymphocytes, characteristic of those found in infectious mononucleosis is

* Many of the tests were generously made by the Blood Laboratory of the Pratt Diagnostic Hospital, Boston.

even more unusual Dameshek⁴ has reported an instance of hemolytic anemia in a patient with infectious mononucleosis who had also received sulfadiazine. A potent iso- and autohemagglutinin especially active at ice box and room temperatures was present in the serum. He felt that the drug played an important role in the production of the anemia. With this exception, no instances of hemolytic anemia occurring in infectious mononucleosis have come to our attention. In their review of hemolytic anemias Dameshek and Schwartz¹ cited none. In his monograph on infectious mononucleosis Bernstein¹⁸ stated that "anemia of any appreciable degree does not appear unless associated with some complicating feature such as hemorrhage of dietary deficiency."

The evidence in this case suggests the possible diagnosis of infectious mononucleosis although it cannot be proved. It was not possible to classify the heterophile antibody by absorption studies.¹¹ Although there was a history of an upper respiratory infection two weeks before the first hospital admission, there was insufficient evidence to establish a diagnosis of atypical virus pneumonia. Since no other etiologic factor for his hemolytic anemia was evident, a causal connection between his anemia and the development of abnormal serum antibodies is suggested, possibly related to a disease resembling infectious mononucleosis.

Another feature of interest is the positive Donath-Landsteiner reaction. Such reactions usually have been found in cases of paroxysmal hemoglobinuria associated with syphilis,⁹ although a few instances of its occurrence in hemolytic syndromes in the absence of syphilis have been reported. In our patient there was no evidence of syphilis. Stats and Wasserman,¹⁹ who estimated that 92 per cent of cases showing a positive Donath-Landsteiner reaction have an associated syphilis, were of the opinion that fundamentally different antibodies are responsible for cold hemagglutinins and a positive Donath-Landsteiner reaction. They found but one case in the literature in which both have been reported²⁰ and refer to one further case with a positive Donath-Landsteiner reaction in which cold hemagglutination at from 0 to 3 Centigrade was observed.²¹

A relationship between the clubbing of the digits and the blood changes is unlikely. The presence of cold hemagglutinins and the occurrence of hemolytic manifestations have been described in patients with peripheral vascular disease, especially of the vasospastic type such as Raynaud's disease.¹⁹ Peripheral osteoarthritis is generally considered to be related to abnormal circulation to the bone, but the association of clubbing with peripheral vascular disease is rare. In the present instance the clubbing preceded the acute hemolytic crisis and progressed after the hematologic abnormalities had disappeared and the hemagglutinins had diminished to a very low titer. This patient showed no evidence of peripheral vascular disease other than a tendency toward moderately cold and cyanotic hands and feet, with hyperhidrosis of the palms developing after his acute hemolytic episode. It is hardly tenable to relate the association of the bone changes to the hemolytic anemia or an illness resembling infectious mononucleosis unless the hypothesis is advanced that there was an underlying circulatory dystrophy with a chronic but minimal production of hemagglutinins which gave rise to a hemolytic crisis when the concentration of these antibodies was increased by the acute disease process.

SUMMARY AND CONCLUSIONS

A case is reported of a young man with acute hemolytic anemia and hemoglobinuria who presented an initial blood picture consistent with infectious mononucleosis, associated with a heterophile agglutination test positive in high dilution, auto-hemagglutinins, active in the cold, at room temperature and at 37 Centigrade, a hemolysin active at 37 C after chilling, requiring the presence of a thermolabile component of serum for hemolysis, a positive Donath-Landsteiner test but no evidence of syphilis. In addition there was clubbing of the digits with certain other roentgenologic changes in the bones, absence of any other etiologic factors known to be concerned with such anemia, uneventful improvement under massive transfusion therapy, with apparent recovery from his hematologic disorder when studied two years later.

ACKNOWLEDGMENT

Our thanks are due to Dr Maxwell Finland and Dr Philip F Wagley for suggestions in preparing this report. We are especially indebted to Dr T Hale Ham for his patient and critical advice and encouragement.

PRIMARY NONFAMILIAL HEMOLYTIC ANEMIA

By J M STICKNEY, M D , AND FRANK J HECK, M D

ALTHOUGH patients with hemolytic anemia are not numerous, they continue to be a problem of special interest and great difficulty. In the majority of cases the disease is of the familial or congenital type. The commonly accepted criteria for the diagnosis of congenital hemolytic anemia include the presence of a microspherocytic blood picture with an increase in signs of regenerative activity, increased fragility of the erythrocytes in varying concentrations of hypotonic saline solution, splenomegaly, an elevated value for indirect serum bilirubin with an increased excretion of fecal urobilinogen, and a history of anemia, icterus, splenomegaly or increased fragility of erythrocytes in other members of the patient's family.

In the differential diagnosis of the different types of hemolytic anemia, the question not infrequently arises as to whether an individual instance of the disease should be regarded as belonging to the congenital or familial type or to the acquired type. As Watson pointed out, there has been a tendency to regard all instances of "primary hemolytic jaundice as of familial or congenital type." There are, however, no clear-cut criteria to which all writers on the subject agree. In some cases in which the family history is negative but other criteria are present, the disease is classified as acquired. It must be admitted that a negative family history is not a definite indication that the disease is of the acquired type since actual investigation of close relatives may reveal such changes as increased fragility of the erythrocytes in the absence of other findings.

In the years 1942 through 1946, at the Mayo Clinic, splenectomy was performed in 22 cases of hemolytic anemia in which no positive family history could be obtained. These 22 cases are the object of our special interest.* As far as could be determined, the hemolytic syndrome in these cases was not secondary to any toxic, infectious or poisonous agent and was not symptomatic and part of a primary disease such as lymphoblastoma, leukemia or hepatic cirrhosis.

We have divided these cases into two groups which happen to be equal in number. In the first group, either microspherocytosis or increased fragility of the erythrocytes or both were found. In the second group, such evidence was not present. The groups are summarized in tables 1 and 2.

REPORT OF SELECTED CASES

Case 3 The patient was a married woman, aged 35. There was no family history of anemia, jaundice or splenomegaly. In November, 1940 she complained of weakness and malaise. She was yellowish and was found to be anemic. On March 10, 1941, the erythrocytes numbered 790,000 and the leukocytes numbered 77,750 per cubic millimeter of blood. Many transfusions were given over a period of one month with moderate benefit. Physical examination disclosed that the spleen was enlarged and extended about 1½ inches below the costal margin.

From the Division of Medicine, Mayo Clinic, Rochester, Minnesota.

* In the years 1942 through 1946, a diagnosis of congenital hemolytic icterus was made in 115 cases at the Mayo Clinic. Splenectomy was performed in approximately 90 of these cases.

When she was admitted to the hospital on May 1, 1941, the hemoglobin value was 11.05 Gm per 100 cc, the erythrocyte count was 3,140,000, the leukocyte count was 7,500 and the reticulocytes numbered 17.6 per cent. Examination of a blood smear showed the picture of congenital hemolytic icterus (microspherocytosis). The serum bilirubin value (indirect reaction) was 0.9 mg per 100 cc of serum. The brom-sulfalein test for liver function did not show any retention of the dye. The fragility of the erythrocytes was normal, initial hemolysis occurred at a concentration of sodium chloride of 0.44 per cent with complete hemolysis at 0.32 per cent. Splenectomy was performed May 5, 1941, the spleen weighed 310 Gm. The patient had a stormy convalescence but was dismissed June 21, 1941, without having been given any transfusion. At that time, the hemoglobin value was 10.6 Gm and the erythrocyte count was 3,700,000.

† Reported in detail in text

When the patient returned to the clinic on August 11, 1941, the hemoglobin value was 10.6 Gm, the erythrocyte count was 3,430,000 and the reticulocytes numbered 6.5 per cent. On September 19, 1941, the hemoglobin value was 10 Gm, the erythrocyte count was 2,610,000 and the reticulocytes numbered 24.1 per cent. The fragility of the erythrocytes had increased, initial hemolysis occurred at 0.5 per cent and was complete at 0.36 per cent. On May 9, 1942, the hemoglobin value was 8.3 Gm, the erythrocyte count was 2,740,000 and the reticulocytes numbered 28.8 per cent. The value for the indirect serum bilirubin was 1.8 mg. Examination of blood smears revealed typical microspherocytosis and increased regeneration of erythrocytes.

In a letter dated February 7, 1945, the patient stated that her hematologic picture was about the same as it had been before splenectomy was performed.

Case 3 illustrates the failure of splenectomy to relieve the anemia. Of interest in this case are the presence of normal fragility prior to splenectomy and an increase in fragility after removal of the spleen. Despite the absence of a family history of hemolytic anemia in this case, the blood picture was considered "typically that of hemolytic icterus" by several observers.

Case 9 A married woman, aged 61, came to the clinic on December 3, 1946. She had been perfectly well until the previous summer, when she had noted a loss of strength and loss of appetite. In the fall of 1946, she had become very thirsty. On October 31, she had been admitted to a hospital because of diabetic coma. The blood sugar value was 310 mg per 100 cc. The presence of diabetes had not been recognized previously. Hematologic examination had disclosed severe anemia, the hemoglobin value had been found to be 5.6 Gm. She had not been jaundiced previously and there was no family history of anemia, jaundice or splenomegaly. The diabetes had been controlled by dietary measures and by the administration of insulin. She had received eight transfusions of blood, 500 cc at each transfusion. The last transfusion had

† Reported in detail in text

‡ Course following splenectomy reported through courtesy of Dr. C. J. Watson

been administered on November 29. Despite the lack of clinical evidence of transfusion reactions, the anemia had not improved.

When the patient came to the clinic on December 3, the hemoglobin value was 4.9 Gm, the erythrocyte count was 1,640,000 and the leukocyte count was 11,200. Examination disclosed moderate icterus. The spleen was greatly enlarged and extended downward to the crest of the ilium. Examination of blood smears disclosed marked microspherocytosis, very active regeneration of erythrocytes, and 40 per cent reticulocytes. The serum bilirubin values were 1.4 mg direct and 3.9 mg indirect. A fragility test showed initial hemolysis at 0.66 per cent and complete hemolysis at 0.36 per cent. The bromsulfalein test for liver function did not disclose any dye retention. During the first forty-eight hours in the hospital, the average amount of fecal urobilinogen excreted each twenty-four hours was 4,800 mg, during the next forty-eight hours, this averaged 1,220 mg. No irregular agglutinins were demonstrable.

The diabetes was carefully controlled. Splenectomy was performed on December 13. The spleen

weighed 1,570 Gm. The postoperative convalescence was uneventful and no transfusion of blood administered. The amounts of urobilinogen excreted in the feces were as follows: on December 17 and 18, 230 mg. per twenty-four hours, on December 19 and 20, 85 mg. per twenty-four hours, on December 21 and 22, 45 mg. per twenty-four hours.

On December 23, the value for the indirect serum bilirubin was 0.6 mg. When the patient was dismissed on January 4, 1947, the hemoglobin value was 8.7 Gm. and the erythrocytes numbered 2,900,000.

In a letter dated March 17, 1947, the patient stated that her blood picture had improved. The hemoglobin value was 13.6 Gm., the erythrocyte count was 3,760,000 and the leukocyte count was 11,600.

In case 9, which belongs to the microspherocytic group, the result has been excellent. In this group, the results of splenectomy as a whole were considered good. In 9 of the 11 cases, the patients were women. There was one death in this group and in one case (case 3) the patient was not improved. In case 11 the patient was improved but did not obtain an excellent result.

Case 13. A boy, aged 11, came to the clinic July 31, 1942. He had had intermittent attacks of jaundice since the age of 2, when he had had a febrile illness which had been diagnosed as Malta fever. The ordinary contagious diseases of childhood, such as whooping cough, measles and scarlet fever, each had been followed by jaundice. The jaundice also had occurred after an infection of the upper part of the respiratory tract.

When the patient was examined at the clinic, he was slightly icteric and the spleen could be palpated 2 inches below the costal margin. The hemoglobin value was 10.5 Gm., the erythrocyte count was 3,270,000 with 10 per cent reticulocytes, and the leukocyte count was 5,400. Examination of a blood smear disclosed active regeneration of the erythrocytes but no microspherocytosis. The indirect serum bilirubin value was 2.2 mg. and the bromsulfalein test for liver function disclosed no dye retention. The fragility of the erythrocytes was normal. It was felt that the patient had hemolytic anemia of an acquired type. Splenectomy was advised.

The patient returned to the clinic May 25, 1944. In August, 1943, he had had an attack of epigastric pain. He had been markedly jaundiced and his temperature had reached 103°F. After ten days he had had a rapid recovery. Examination disclosed hematologic findings as they were at the time of the patient's first visit to the clinic with the exception that the indirect serum bilirubin value was 5.5 mg. Splenectomy was performed on May 29. The spleen weighed 266 Gm. When the patient was dismissed, the value for the hemoglobin and the erythrocyte and leukocyte counts were the same as they had been when the patient came to the clinic but the indirect serum bilirubin value had dropped to 0.5 mg.

He returned to the clinic July 19, 1944, because of an attack of pain in the upper part of the abdomen and jaundice. At this time, the hemoglobin value was 12.3 Gm., the erythrocyte count was 3,880,000 and the leukocyte count was 11,800. Microcytosis of the erythrocytes was observed for the first time. No change in the hematologic findings was observed when the patient was seen again on August 8, 1946. Attacks of jaundice had continued to occur. The patient's growth has continued in an apparently normal manner.

Case 15. A married woman, aged 21, came to the clinic April 20, 1945. In January, 1944, she had had a miscarriage at the fourth month of pregnancy. During the pregnancy, her parents had thought that she had appeared yellow. After the miscarriage, she had lost weight and had become very weak. She had been treated for anemia. There was no family history of hemolytic anemia. Serologic tests for syphilis on both the blood and spinal fluid had been strongly positive, and antisyphilitic treatment had been administered intramuscularly. There was no personal or family history of syphilis and the patient denied the possibility of contact infection. Between March 27 and April 12, 1945, she was given a total of 2,500 cc. of blood in nine transfusions. She had been told that her hemoglobin value was lower after these transfusions than it had been previously.

When she was examined at the clinic, the hemoglobin value was 8.8 Gm., the erythrocyte count was 2,520,000 and the leukocyte count was 8,200. Examination of a blood smear revealed a marked increase in the regeneration of the erythrocytes and a regenerative macrocytosis. There was abundant myeloid

immaturity but no evidence of microspherocytosis. The indirect serum bilirubin value was 1.6 mg. The fragility test revealed that hemolysis began at 0.44 per cent and was complete at 0.34 per cent. The brom-sulfalein test disclosed no dye retention. The Kline, Kahn, Hinton and Kolmer serologic tests for syphilis were negative.

On May 2, the hemoglobin value was 4.5 Gm, the erythrocyte count was 1,470,000 with 32.2 per cent reticulocytes, and the leukocyte count was 7,500. The amounts of urobilinogen excreted in the feces were as follows: On May 1 and 2, 894 mg per twenty-four hours, on May 3 and 4, 642 mg per twenty-four hours. A transfusion of 500 cc of blood was administered on three occasions between May 3 and May 9. Splenectomy was performed on May 9. The spleen weighed 670 Gm. Another transfusion of blood was given on May 21.

The patient was greatly improved when she returned to the clinic for examination on October 24, 1945. The hemoglobin value was 12.7 Gm, the erythrocyte count was 4,620,000 with 8.6 per cent reticulocytes and, the leukocyte count was 12,900. In the blood smear there was active regeneration of the erythrocytes with many macrocytes. The amount of urobilinogen excreted in the feces was determined for a period of four days. The average amount was 147 mg per twenty-four hours. The indirect serum bilirubin value was 0.45 mg.

On March 25, 1947, the patient's family physician informed us that the hemoglobin value was 78 per cent and that the erythrocyte count was 4,120,000.

In the group of cases without significant microspherocytosis, females again predominated. The higher incidence of this disease among females has also been noted by Fowler. In this group, the results have not been as good as they were in the microspherocytic group although the number of cases is not large enough to draw definite conclusions. However, the results are encouraging enough to warrant further trial of splenectomy. A longer period of observation is desirable to determine how frequently hemolytic episodes may occur after operation.

COMMENT

In recent years several excellent reviews dealing with hemolytic anemia have appeared.^{1, 2, 7} Watson has classified the hemolytic anemias as microcytic (familial or congenital) and macrocytic (secondary or acquired). He stated that in all cases of the acquired type of the disease the erythrocytes are at least slightly larger and often much larger than the normal. Dameshek and Schwartz and Singer and Dameshek, pointed out that in some cases of acquired hemolytic anemia, spherocytosis and increased hypotonic fragility are present, although a "pseudomacrocytic" blood picture may be seen. Fowler found that spherocytosis was not consistently present in a group of cases of acquired hemolytic anemia and that macrocytosis was more frequently encountered.

All of our cases were examples of primary nonfamilial hemolytic anemia so far as we could determine. Microspherocytosis was not present in half of these cases but with one exception (case 13) we could not classify them as cases of macrocytic anemia. There was a considerable number of macrocytes in some of the smears but many of them were regenerative or polychromatophilic erythrocytes.

Agglutinins and hemolysins may be etiologic factors in a hemolytic syndrome. In two of our cases (cases 14 and 22) iso-agglutinins of an abnormal type were present. In each instance, the patient's serum agglutinated his own erythrocytes. In another case (case 4), an Rh negative patient had a high Rh antibody titer due to previous transfusions of Rh positive blood. Although the blood picture was micro-

spherocytic, it is possible that this antibody titer may have been the cause of hemolytic anemia. In any event, improvement did not occur until splenectomy was done. At the present time, a more intensive search for irregular agglutinins and hemolysins is being carried out in certain cases of hemolytic anemia.⁵

Several authors have emphasized the dangers of severe hemolytic reactions following blood transfusion in hemolytic anemia. In one of our cases (case 10), death was probably due to a hemolytic transfusion reaction after operation. We have noted any severe exacerbation of the hemolytic process in the other cases but have been impressed with the failure of transfusion to benefit the patient, especially before splenectomy.

We have found it difficult to correlate the degree of anemia with the severity of the jaundice. In one case (case 4) as long as the patient was severely jaundiced the anemia was relatively mild. When the severity of the jaundice decreased, the concentration of hemoglobin decreased rapidly. This inverse relationship has been noted by Watson and Fowler.

In several of our cases bone marrow was examined. A definite hyperplasia of normoblastic cells was seen in each instance. No megaloblasts were found.

Although not common, leukopenia and thrombocytopenia may accompany hemolytic anemia. Doan and Wright have recently reported this phenomenon as a pancytopenia. In case 14, the number of leukocytes ranged from 3,100 to 5,000 and the number of thrombocytes from 65,000 to 75,000 per cubic millimeter before splenectomy. Both were normal or increased in number after operation.

In a case not included in this series splenectomy was performed for what appeared to be a primary hemolytic anemia. The blood picture was subsequently that of chronic myelogenous leukemia. At the time of the original examination, there was not as much myeloid immaturity as there was in the blood of many of the patients in the present series. The sternal marrow was hyperplastic and could not be distinguished from nonleukemic hyperplastic marrow.

Splenectomy may be of definite benefit in symptomatic hemolytic anemia when the progress of the primary disease is not rapid. Recently, a woman who was 60 years of age came to the clinic because of weakness of six months' duration. The hemoglobin value was 8.3 Gm., the erythrocyte count was 2,250,000 with 15 per cent reticulocytes. A spleen which weighed 1,125 Gm. was removed and a diagnosis of follicular lymphoblastoma was made. There were no enlarged lymph nodes. One year later, the patient, who had regained her good health, returned because of enlarged axillary and inguinal lymph nodes. The hemoglobin value then was 11 Gm. and the erythrocyte count was 4,150,000. Biopsy of a lymph node confirmed the previous diagnosis and for the first time roentgen therapy was started. The splenectomy had relieved the weakness and anemia.

SUMMARY

In our experience, in half of the cases of primary hemolytic anemia in which there is no family history of anemia, jaundice or splenomegaly, examination of the blood disclosed microspherocytic erythrocytes and increased fragility of erythrocytes. The results of splenectomy in these cases are better than in those in which

microspherocytosis is absent True macrocytosis was observed in only one instance Females predominated in both groups of cases Agglutinins and hemolysins have not appeared to play any significant role in the production of the hemolytic syndrome in our cases We do not feel justified in expressing an opinion as to whether the microspherocytosis indicates a familial or congenital blood disorder From a practical standpoint, it makes no great difference since splenectomy should be considered seriously in any case of chronic primary hemolytic anemia It may be of value in some cases of secondary or symptomatic hemolytic anemia

THE GENETIC RELATION AND CLINICAL DIFFERENTIATION OF COOLEY'S ANEMIA AND COOLEY'S TRAIT

By GENEVA A DALAND, B S , AND MAURICE B STRAUSS, M D

IN 1925¹ the late Thomas B Cooley first described the severe and generally fatal anemia that is now variously known as Cooley's Anemia, Mediterranean anemia and thalassemia. Since then numerous workers¹⁻¹⁰ have reported cases of a mild blood disorder which resembles Cooley's anemia but is not associated with the symptoms or disability. This disorder, found almost exclusively in Italian and Greek families, is characterized by microcytosis and hypochromia with marked variation in the size and shape of the erythrocytes and by increased red cell resistance to lysis in hypotonic salt solution. The hemoglobin values are either normal or moderately reduced while the red blood cells are generally increased in number. For reasons to be discussed later the term "Cooley's Trait" is proposed for this disorder and will be used throughout this paper. Neel and Valentine¹¹ have estimated that this condition is present in 4 per cent of persons of Italian ancestry in Rochester, N Y , and one of us has noted it frequently as an incidental finding in soldiers of Mediterranean ancestry in an Army General Hospital.

Since earlier publication,⁵ 4 additional families have been studied, one family including 3 cases of Cooley's anemia. One of the patients with Cooley's anemia has given birth to a living child, an event thus far unreported. This child exhibits Cooley's trait.

It is the purpose of this publication to present the hematologic and genetic data obtained from the examination of these families, to clarify further the inheritance of both Cooley's trait and Cooley's anemia and to emphasize the clinical and hematologic differentiation of the two conditions.

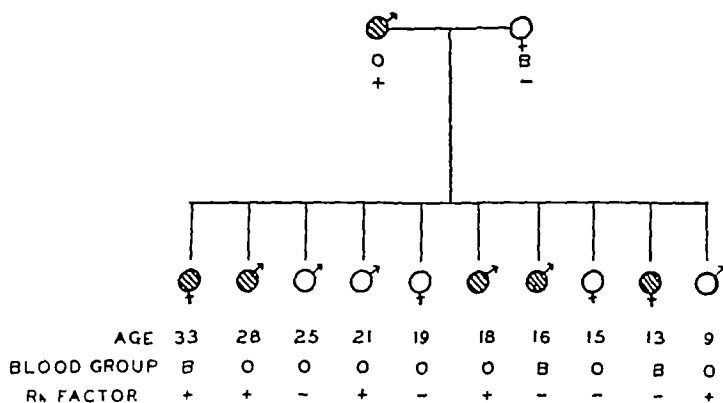

OBSERVATIONS

Family Ca A 16 year old boy of Italian parentage came under observation during an acute attack of rheumatic fever. He was found to have a hypochromic microcytic anemia with marked variation in cell size and shape and increased red cell resistance to lysis by hypotonic salt solution. Twelve grains of ferrous sulfate daily for one month failed to alter his blood values. Blood studies on the patient, on the patient's father, mother and 9 siblings are recorded in table 1 and figure 1. All the members of the family were healthy and completely asymptomatic. No member was known to have been anemic or seriously ill.

Family Cr A 32 year old woman first came under observation after she had been unsuccessfully treated for a mild anemia for several years. Her blood study exhibited all the characteristics of Cooley's trait. Accordingly other members of the family were examined. The data are shown in table 2 and figure 2. Both parents had been born near Naples, Italy. The father had died many years before. The mother died of pneumonia in 1941. In 1938 she had been observed to have undue variation in the size and shape of her erythrocytes and considerable basophilic stippling. When she had pneumonia she was anemic and nucleated red blood cells were observed in stained blood films.

Family Sp This family was reported in detail from this laboratory by Spodaro and Forkner² in 1933.

From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, the Medical Service, Cushing Veterans Administration Hospital, and The Department of Medicine, Harvard Medical School.

under the title Benign Familial Polycythemia, but since it is now believed that this condition is identical to Cooley's trait the essential data are presented in table 3 and figure 3

Family Pa The oldest daughter of this family was first observed at the Massachusetts General Hospital in 1934, when she was 19 years of age. At this time she had acute pyelonephritis and in addition

discovered to have the characteristic blood picture of Cooley's anemia, as well as jaundice, splenomegaly and changes in the bones. She maintained approximately the same blood level for the next five years but died with severe anemia a fortnight after the birth of a child. At the time of delivery her red blood count was reported to be 1.12 million per cu mm and the hemoglobin 3.9 Gm per 100 cc.

In 1934, when the diagnosis of Cooley's anemia was first made on the above patient, her parents and 5 siblings were examined. At that time a brother, aged 7, and the youngest sister, aged 16, were considered to have Cooley's anemia, but the mother, father and 3 other sisters were believed to be normal. On subsequent examination by the authors, however, all but one sister were found to have Cooley's trait (table 4, fig. 4). The brother had many hospital admissions and finally died at the age of 11. His autopsy findings were typical of Cooley's anemia.

The youngest sister has been followed in the Thorndike Memorial Laboratory since 1938, during which time she has continued to present a characteristic picture of Cooley's anemia. In March 1946 she was delivered of a male infant whose blood has been examined on several occasions. On October 1946 his red cells numbered 5,330,000 per cu mm and his hemoglobin was 9.4 Gm per 100 cc. Following treatment with iron for two months the red cell count was 6,100,000 and the hemoglobin 14.0 G. His blood films are definitely abnormal, showing variation in size of the red cells, variation in intensity

FIG. 2. Family Cr

of staining, microcytes, occasional pencil forms and fragmented forms. No stippled cells were seen. This picture has been maintained throughout the observations and is a distinctly unusual picture when the red count and hemoglobin are so high. With the exception of frequent colds, he has been entirely well. His father has an entirely normal blood (table 4).

LITERATURE

During 1940 and 1941, three groups of investigators independently described the mild blood disorder illustrated by the cases presented above. Wintrobe and his co-workers³ considered the condition to be a benign form of Cooley's anemia. Dameshek⁴ described it as "target cell" anemia. These authors, both then and in later publications,^{9, 14} emphasized the existence of a continuous series of conditions from the very mild cases of Cooley's trait to the most severe Cooley's anemia. The present authors⁵ termed the mild disorder "Familial Microcytic Anemia," stressing the fact that although it resembled Cooley's anemia, clinical and hematologic differentiation was not difficult. It was further stated that the mild disorder

appeared to be inherited as a dominant character whereas Cooley's anemia was believed to be recessive^{15 16} Although Angelini,¹⁷ and independently Caminopetros,¹⁵ had observed that the parents and siblings of patients with Cooley's

anemia frequently exhibited increased red cell resistance to lysis by hypotonic salt solution, it was not until Wintrobe^{14*} pointed out that in two different patients with Cooley's anemia *both* parents exhibited the mild blood disorder, that the genetic relationship between the two conditions became apparent. Wintrobe's observations were confirmed* by Smith,^{7, 8} Dameshek⁹ and Valentine and Neel,¹⁰ who in 1944 published a thorough discussion of the subject and added data from four additional families.

DIFFERENTIATION OF COOLEY'S TRAIT FROM COOLEY'S ANEMIA

Although it is possible by proper selection of cases to show a continuous series of conditions grading from the most severe type of Cooley's anemia fatal in early life to the most mild instances of Cooley's trait in which there is no anemia whatsoever, it is our impression that generally the differentiation of the two conditions is not difficult although both are characterized by hypochromia, microcytosis,

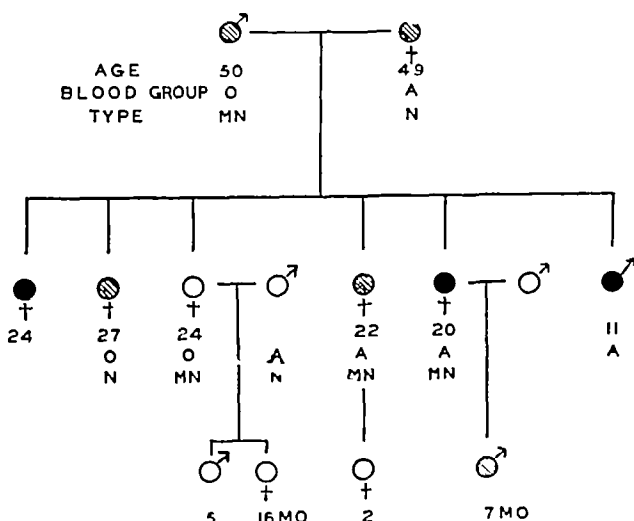

FIG. 4 *Family Pa*

anisocytosis and poikilocytosis out of proportion to the hemoglobin levels. The blood pictures fall into two fairly well defined groups, one severe and generally fatal, the other benign. † Correlated with these two blood pictures may be found marked clinical signs and symptoms in the case of Cooley's anemia, or their absence or minor nature, in Cooley's trait. The differential diagnostic findings between Cooley's anemia and Cooley's trait are shown in table 5.

* Although the matter of priority as regards this particular point is of little significance, it should be pointed out that Dameshek (Hemolytic Syndromes Exhibit American Medical Association, June 1942. Privately printed 1942, and Bull. New England Med. Centre 467, 1942) also clearly pointed out this hereditary mechanism. These observations were made independently and were therefore not confirmatory, as stated *Editor*.

† Attempts to divide this entire disease syndrome into two groups, one severe and one benign, are not always successful, since a number of intermediate forms with moderate anemia, splenomegaly, and icterus are found. It seems hardly desirable to designate cases of well-defined anemia as trait, especially since various symptoms referable to the anemia are present. *Editor*.

GENETIC CONSIDERATIONS

Three main types of inheritance could explain the relationship between Cooley's anemia and Cooley's trait¹⁰

I *A single dominant factor variably expressed* An example of this type of inheritance is found in the variable severity of hemophilia which the sons of one mother may exhibit, each of whom owes his disease to an identical gene. If this

mode of inheritance were involved, Cooley's anemia should appear in families in which only one parent exhibited a blood abnormality. However, in essentially every case in which both parents of a patient with Cooley's anemia have been

examined, both have shown the mild disorder. Since, in accord with this theory, only one parent need be affected, and since marriages between two affected individuals should be much rarer than between one affected and one normal person, most cases of Cooley's anemia would be the issue of the latter type of union.

2 *The simultaneous presence of two nonallelomorphic dominant factors, one inherited from each parent*, as suggested by McIntosh and Wood,¹⁸ would result in Cooley's anemia. This theory requires the assumption that each factor alone leads to the same mild somatic condition, which Valentine and Neel¹⁰ consider improbable. However, it may be noted that in *Drosophila* a number of different factors may lead to the identical eye color. There are other more complex types of inheritance which may be considered in which two nonallelomorphic factors are required for the development of the full-blown character and in which heterozygosity leads to a partial abnormality. For example, "ski-wing" in *Drosophila* results from homozygosity of two genes in the second and third chromosomes. If the gene in the second chromosome is heterozygous and the gene in the third chromosome homozygous, a mild form of ski-wing results.

3 *A single 'incomplete' recessive or dominant factor*. Under this type of inheritance the heterozygote would exhibit Cooley's trait and the homozygote, Cooley's anemia.

The data presented here, together with the extensive statistical analysis of Valentine and Neel^{10, 19} are compatible with either the second or the third mode of inheritance.

NOMENCLATURE

Spodaro and Forkner² termed this mild blood disorder "benign familial polycythemia." Since polycythemia is not necessarily present this designation is unsuitable. The present authors have called it "familial microcytic anemia,"⁵ a name which must be rejected since anemia may be absent.

Wintrobe et al.² called this condition "a familial hemopoietic disorder in Italian adolescents and adults resembling Mediterranean disease (thalassemia)." Dameshek⁴ referred to it as "target cell anemia." However, target cells are encountered in many conditions and may be artificially produced in vitro by suspending normal cells in plasma or serum rendered hypertonic.²⁰ Later Dameshek used the designation "familial Mediterranean target-oval cell syndromes."⁹ Since cases have been reported in English, Negroes, Chinese, Turkish, Spanish and others²¹ and since there is a distinct blood disorder characterized by oval erythrocytes²² this name does not appear suitable. Valentine and Neel's¹⁰ terminology, thalassemia major and thalassemia minor for the severe and mild disorders, has much in its favor. However, the wide distribution of these conditions, even if their common origin at one time was the Mediterranean and the cumbersome terms have led the present authors to call the conditions "Cooley's anemia" and "Cooley's trait," bearing in mind the analogous sickle cell anemia and sickle cell trait. It is not implied that sickle cell anemia and sickle cell trait bear the same genetic relation as Cooley's anemia and Cooley's trait. Although eponymic nomenclature is in general undesirable, it may be pointed out that a number of syndromes such as Graves' disease, which may occur without goiter, without hypothyroidism, without ophthalmopathy, defy accurate descriptive terminology.

SUMMARY

- 1 Four additional families illustrating the clinical and genetic relationships of Cooley's anemia and Cooley's trait have been presented
- 2 Blood findings in an offspring of a patient with Cooley's anemia are recorded
- 3 The asymptomatic nature of Cooley's trait and its differentiation from Cooley's anemia has been emphasized
- 4 The inheritance of Cooley's trait and Cooley's anemia may be best explained in terms of an incomplete dominant or of the simultaneous appearance of two nonallelomorphic genes

ACKNOWLEDGMENT

We are indebted to Dr. John H. Linner for many of the observations on the Ca family and to Mrs. Clara Gillette for observations on the Cr family.

STUDY OF THALASSEMIA MINOR IN THREE GENERATIONS OF AN ITALIAN FAMILY

By ROBERT W HEINLE, M D , AND MARGARET RUTH READ, M D

A CONSIDERABLE knowledge concerning the heredity and transmission of Cooley's erythroblastic anemia, or thalassemia, has accumulated during the past twenty years but there is still need for more complete data and further genetic studies of families showing the trait

In 1927, Cooley¹ reported his observations on erythroblastic anemia occurring in Mediterranean peoples. He concluded that the anemia was congenital, but in spite of frequent familial occurrence, he doubted that heredity was a factor since the patients died before puberty and so could not transmit the disease

It was recognized for the first time in 1937 that a mild, but similar, type of anemia occurred in parents and siblings of individuals with Cooley's anemia. Angelini (quoted by Wintrobe and his associates²) observed that in some instances, the erythrocytes of apparently healthy parents and siblings of patients with Cooley's anemia showed decreased fragility when tested in hypotonic saline. Caminopetros³ independently confirmed this observation in 1938

Two years later, Wintrobe and co-workers,² Dameshek⁴ and Strauss and co-workers⁵ described a mild form of microcytic hypochromic anemia, resistant to iron therapy, and occurring in Italian families. The anemia was characterized by the frequent occurrence of increased numbers of erythrocytes, with absolute and relative reduction of hemoglobin, bizarre forms of erythrocytes and decreased fragility in hypotonic saline. These authors variously termed the dyscrasia as 'target cell anemia,' "familial microcytic anemia" and 'anemia of adults resembling thalassemia'. It was not immediately apparent whether this disease was related genetically to Cooley's Mediterranean anemia, but such a possibility was suggested

Wintrobe⁶ later confirmed Angelini's and Caminopetros' observation of decreased fragility of erythrocytes in the parents of patients having Cooley's erythroblastic anemia and further pointed out that the blood picture in the parents was identical with the familial microcytic hypochromic anemia which he had previously described.²

In 1942 and 1943, Dameshek⁷ described several anemic states of varying degree of severity ranging from Cooley's erythroblastic anemia to conditions with mild hypochromic anemia, target, oval and stippled cells and increased resistance of the erythrocyte to hypotonic saline. He confirmed the findings of other workers in demonstrating that such blood changes occurred in both siblings and parents of patients with thalassemia. Smith⁸ also demonstrated similar changes in the blood of siblings of patients with Cooley's anemia and discussed the diagnosis of the "trait" or mild form of the disease

Valentine and Neel,⁹ in reporting studies on parents and siblings of 3 patients with thalassemia and of one person with a similar mild condition, considered the hereditary aspects of the disorder and emphasized the problem of differential diagnosis and the clinical significance of the mild form of the anemia. By statistical analysis of cases collected from the literature, they concluded that the bulk of evidence favored the hypothesis that the mild, microcytic hypochromic anemia was a form of thalassemia which resulted from heterozygosity for a factor which, when homozygous, caused full-blown thalassemia. These authors suggested the term "thalassemia major" for the severe erythroblastic anemias as originally described by Cooley and "thalassemia minor" for the mild microcytic hypochromic anemias characterized by target cells, oval cells and increased resistance of the erythrocytes to hypotonic saline.

Cooley¹⁰ has more recently described a microcytic hypochromic anemia occurring only in males with transmission through the females in a family of Dutch descent. His conclusion that the disease was due to a fundamental constitutional defect of the hematopoietic system unrelated to familial microcytic anemia may be open to some doubt.

In 1945, Neel and Valentine¹¹ reiterated their views regarding "thalassemia major and minor" and the inheritance of the conditions. From a study of a portion of the Italian population of Rochester, N. Y., they concluded that thalassemia major occurred in about 0.042 per cent and thalassemia minor in about 4 per cent.

The present report deals with the occurrence of a microcytic hypochromic anemia in 9 of 13 members of a family of Sicilian descent over a span of three generations. The study was initiated when one of the members of the second generation was found to have a hypochromic anemia which did not respond to iron.

CASE REPORT

Patient L. O., a 37 year old unmarried woman of Sicilian descent, was first seen by us on September 18, 1945, complaining of feeling faint. She had first noted this two years previously and was told by a physician that she had anemia. Therapy with iron, liver extract injections and oral liver-iron preparations were without symptomatic or hematologic benefit. She later experienced fatigue and a sensation of twitching in the left leg and hand, although no muscle contractions were ever visible. She had been studied at another hospital on two occasions but was not aware that any diagnosis was made. History of anemia in other members of her family could not be elicited.

On physical examination, the positive findings consisted of slight pallor of the mucous membranes, a metallic first heart sound at the mitral area, bilateral positive Hoffman reflex, and a nystagmus on right lateral gaze with fast component to the right. The liver and spleen were not palpable.

She had been examined by a neurologist who was unable to explain the symptoms and signs and who considered that they might be secondary to the anemia. They have never been adequately explained.

Laboratory data. Erythrocytes 5,570,000 per cu. mm., hemoglobin 10.4 Gm. per 100 cc., leukocytes 5,300, hematocrit 36, mean corpuscular volume 64.9 cu. microns, mean corpuscular hemoglobin 18.7 micromicrograms, mean corpuscular hemoglobin concentration 28.9 per cent. Differential blood count: 58.5 per cent neutrophils, 3.5 per cent eosinophils, 0.5 per cent basophils, 31.0 per cent lymphocytes, 6.5 per cent monocytes. No nucleated red cells were seen. The erythrocytes showed marked anisocytosis and poikilocytosis, and were microcytic hypochromic. Numerous target cells and a few oval shaped cells were present (figs. 1 and 2). The platelets were slightly increased in number. Sedimentation rate was slower than normal, the corrected value being less than zero. This finding was due presumably to delay in rouleau formation resulting from the abnormal shape of the erythrocytes.

* S-2 = spouse of member of second generation
† Platelets estimated from smear, increased in number
‡ Platelets estimated from smear, normal in number

She was seen again one month later with the same complaints and laboratory findings There had been no response to iron therapy Saline fragility test showed beginning hemolysis at 0 38 per cent at

complete hemolysis at 0.20 per cent. X-rays of the skull, humerus and hands showed a slight degree of demineralization without specific changes.

It was felt that much of the patient's symptomatology was on a nonorganic basis, especially since she was inclined to place the blame for her symptoms on her work (machine operator), and since it seemed likely that the anemia had antedated the onset of her symptoms.

A tentative diagnosis of familial microcytic anemia was made and it was arranged to study other members of her family.

FIG. 4. Patient S. S., third generation. Peripheral blood showing hypochromia, target cells, oval cells, and poikilocytes. $\times 640$.

Table 1 and figure 3 show the results of findings in the other living members of the family, including the parents of the patient, her brothers and sisters, and the third generation of her nieces and nephews, in addition to two of three spouses of members of the second generation. The patient's father, P. O., had died at age 63 years, two years before we saw the patient, L. O., but he had been admitted to an outside hospital in 1942 where blood studies had been performed and where a diagnosis of duodenal ulcer and nonfunctioning gall bladder had been made. His laboratory findings were made available to us and are recorded in table 1.

A sister of the patient, L. O., died at age 5 years of burns. She was never investigated for anemia and was thought to have been entirely well. All the other members of the family, including the spouses, were in good health.

It will be noted (table 1, figure 3) that the parents of the patient, all 5 living members of the second generation and 2 of 5 members of the third generation apparently had identical blood findings. The number of target cells and bizarre forms varied somewhat but the essential features were identical. A photomicrograph of the blood of S S, a 10 year old nephew of the patient (L O) is shown in figure 4 and a photomicrograph of the blood of M S, aged 21, a niece of the patient is shown in figure 5.

The 9 affected members of this family were individuals with apparent good health, capable of doing a full day's work without unusual fatigue. There were no signs or symptoms which would have led to a diagnosis of a blood dyscrasia except the presence of palpable spleens in 5 of the 9 affected individuals.

FIG 5 M S, third generation. Peripheral blood showing target cells, oval cells and poikilocytes $\times 640$

Thus, such cases are usually discovered coincidental to examination for other reasons or during a special study of a group of patients. The individuals are of Italian or Sicilian descent. The spleen is palpably enlarged in some cases but the enlargement is not great as compared with others of the blood dyscrasias, and the finding is not constant. Palpable enlargement of the liver did not occur in this series.

The erythrocyte count is frequently elevated above normal and in this series was as high as 7,000,000 per cu mm. The hemoglobin content and hematocrit values are low, of course, so that the mean corpuscular volume and mean corpuscular hemoglobin values are considerably less than normal. The mean corpuscular hemoglobin concentration is not reduced as much, a further indication of the microcytosis. Examination of the blood films confirm these data. Hypochromia is obvious in addition to which there are variable numbers of target cells, and cells of bizarre shape. Some of the smaller erythrocytes appear to be well-filled with hemoglobin.

The saline fragility test was abnormal in all 9 of the affected individuals in this series. In some, the

molysis began at about normal concentrations, 0.42 to 0.46 per cent saline, indicating that a part of the population of erythrocytes had normal osmotic properties and were, presumably, of normal shape. In some, hemolysis began at much lower levels, indicating that all of the erythrocytes were flatter than normal. Complete hemolysis occurred at lower than normal concentrations in all cases, ranging from 0.20 to 0.24 per cent with the exception of the mother who had complete hemolysis at 0.30 per cent, only slightly below normal.

In this series there was no increase in reticulocytes, stippled erythrocytes or nucleated red cells. The leukocyte and differential blood counts were normal in all of the affected individuals. In some cases, the number of platelets appeared to be slightly increased as estimated from the blood films. Platelet counts were not made. X-rays of bones showed no specific lesions in the one case (L. O.) on whom they were made. The anemia is completely resistant to iron therapy.

DISCUSSION

This asymptomatic, microcytic hypochromic anemia is not in itself of great importance except as the condition may fail to be diagnosed or diagnosed incorrectly. Of significance, however, is its relation to thalassemia major, a more severe disease, usually fatal during childhood. In this series, two Italians with the mild form of the disease, thalassemia minor, produced 6 children, 5 of whom are known to have had an identical mild form of the condition. It would appear at first hand, therefore, that the trait, dominant in both the parents, was simply inherited by the children. That such is not the case, however, has been demonstrated by the work of others and is further confirmed by the occurrence of the condition in the third generation of this series, in which only 2 of 5 were affected.

From the literature, and from this series, it seems probable that the severe form of the anemia, thalassemia major, results from homozygosity of an inherited factor while the milder form, thalassemia minor, results from heterozygosity of the same factor. According to this idea, both parents were heterozygous, since they had the mild form of the disease. They would be expected to have children who were homozygous (thalassemia major), heterozygous (thalassemia minor) and completely free of the trait in a ratio of 1:2:1. That all 5 of the second generation studied had thalassemia minor, signifying heterozygosity, was therefore apparently due to chance occurrence in a small sample. The statistical probability of this occurrence being due to chance is 1 in 14 (P value about 0.07, borderline significance).

The third generation in this series, however, fits the idea very well. In this case, if one parent were heterozygous and the other free of the trait, half the offspring would be expected to be heterozygous (thalassemia minor) while half would be expected to be unaffected. The occurrence of thalassemia minor in 2 of 5 members of the third generation agrees with this concept.

The mechanism of production of the abnormal erythrocytes is not understood. Valentine and Neel¹² were able to produce target cells experimentally, both in vitro and in vivo, by increasing the tonicity of the solution in which the cells were suspended. Whether this represents the natural mechanism of production of target cells has not been established.

SUMMARY

1. Three generations of a family of Italian descent were studied. Nine of 13 members were found to have thalassemia minor.

2. Genetic studies indicate that this mild, microcytic hypochromic anemia characterized by the presence of target and elliptical cells and other bizarre forms and by increased resistance to hypotonic saline, results from heterozygosity of an inherited factor, which, when homozygous, produces thalassemia major or Cooley's Mediterranean anemia

3. If individuals heterozygous for this factor (thalassemia minor) marry other heterozygous individuals, one quarter of the offspring can be expected to be homozygous (thalassemia major), one half heterozygous (thalassemia minor) and one quarter free of the trait

4. The presence of thalassemia minor apparently did not interfere with the general health of affected members of this family and did not appear to shorten life expectancy. The importance of the condition lies in its relation to thalassemia major

PROPHYLAXIS OF HOOKWORM ANEMIA-DEFICIENCY DISEASE

By W O CRUZ, M D , AND R PIMENTA DE MELLO, M D

IN VIEW of present knowledge of hookworm anemia, it has become evident that, qualitatively and in conjunction with helminthic infestation, deficient nutrition is of importance in the genesis of this disease. The possibility of curing the anemia, even though the intestinal parasitism remains, has provided us with the opportunity of observing which symptoms and clinical signs result from a hemoglobin deficiency and which are caused directly by the presence of the helminths. Contrary to what might be expected, with the exception of intestinal hemorrhages and eosinophilia, all other pathologic changes disappeared as the blood became normal. So great is the importance of these symptoms and signs that yield with the treatment by iron, and so insignificant are those that remain, that we should, in this case, consider the anemia not as a syndrome connected with the signs, but as the disease itself. The specificity of the treatment of anemia by iron and the astonishing nature of the cure are the usual characteristics of conditions of deficiency.

Up to the present time, prophylaxis of hookworm anemia has been considered as the prophylaxis of a disease which is strictly parasitic in origin. The methods are difficult and costly, amounting almost to radical changes in the firmly established habits of a population (use of shoes) or sanitary engineering measures amounting almost to sudden civilization of backward zones (construction of privies, etc.). These classic methods of prophylaxis, consisting in avoiding the infestation of man by *Ancylostoma*, have been of no practical effect with respect to the incidence of the anemia.

If we consider the prophylaxis from the point of view of the second agent in the etiologic complex of hookworm anemia, i.e., qualitative nutritional deficiency, a different plan of prophylactic campaign can be outlined. The application of iron in prophylaxis is not sufficient to eliminate completely the disease from a community, and in addition, it requires periodic application. On the other hand, this method is one of the easiest to apply, when it is duly supported by the proper public health laws.

Following these principles, Cruz and de Mello¹ attempted to create the bases for a prophylaxis of hookworm anemia considered as a deficiency disease (similar to the prophylaxis of endemic goiter). This consisted in adding an iron salt, hematologically active, to the foods habitually eaten by the lower social classes. The difficulties encountered were considerable, as compared with the prophylaxis of endemic goiter. In the latter, 0.005 Gm. of potassium iodide are sufficient, whereas in hookworm anemia we had to use a much higher dose of usable iron salt. Various trials were made, not only for choice of food, but also of the iron salt with highest therapeutic value and stability. The authors concluded that the mixtures of ferrous sulfate with manioc flour and of ammoniacal ferric citrate with bean gravy were

From the Hematology Department Instituto Oswaldo Cruz, Rio de Janeiro, Brazil

Aided by a grant from Dr. Guilherme Guinle

sufficient not only to cure, but later to prevent the fall of blood values during long periods of time, in individuals who were heavily infested. Various cases were described,¹ a summary of which may be seen in table 1.

With the various experimental mixtures used, it was attempted to fulfill the following requirements: taste, stability, appearance, hematologic efficiency, and low cost. Only two were found to be satisfactory: ferrous sulfate mixed with manioc flour and ferric ammonium citrate, brown, added to bean gravy. The salts

listed in table 2 were also tried, but did not fulfill the requirements and their use was not continued.

With regard to the infestation index listed in table 1, we should keep in mind that, according to present knowledge, the contribution of the helminths to the formation of anemia appears to be exclusively through their blood-sucking activities. The hemorrhages caused by this action have a distinctive significance in the physiology of the blood. The organism reacts in various ways according to the hematic constituents lost in a hemorrhage. It seems to possess an unlimited quantity of protein for reconstitution of the red blood cell stroma, of globin, and of amino radicals present in the chemical structure of heme. This is not the case with

relation to the basic metal for the respiratory function This metal is a vital raw material for reconstitution of respiratory pigment, and the organism is entirely dependent on the reserves supplied to it by nutrition to maintain a normal hemo-

globin metabolism Accordingly, when the helminths withdraw blood from the body, they withdraw essentially the iron metal Therefore, each helminth represents a unit of consumption in the iron balance in the body This unit will increase in importance in proportion to the decrease of iron in the circulation of the host It is known that in mammals the total amount of blood is approximately 10 per

cent of the body weight. Hence, the damage caused by a worm will be less important in an adult of 60 kilos than in a child of 20 kilos. This means that the intensity of infestation can be expressed only by a relationship between the number of worms living on the intestine and the mass of circulating blood, or roughly the body weight of the host. Based on these data, we suggest that the intensity of infestation from *Ancylostoma* be figured according to table 3.

In order to determine approximately the number of helminths per kilo of body weight, based on egg counts, the following formula is used $\frac{N}{18P}$, in which N represents the number of eggs per gram of feces and P the weight of the individual expressed in kilograms. Usually the infestation occurs with an equal number of male and female helminths, and as the females of the *Necator* are responsible for eliminating 36 eggs per gram of stools, we should divide the egg count by half of 36, which explains the factor 18 in the denominator of the formula. Therefore, for

TABLE 3

Intensity of infestation—Groups	Helminths per kilo of body weight
I	0
II	0-0.9
III	1-4.9
IV	5-9.9
V	10-14.9
VI	over 15

example in a child, 31 kilo body weight, with 5,000 eggs per gram of feces we have $\frac{5000}{560} = 8.9$ helminths per kilo of body weight, a case belonging to group IV of our classification.

Following these studies on the administration of iron in the prophylaxis of hookworm anemia considered as a deficiency disease, it would doubtless be very important to determine the minimum dose of salt to be used, in order to maintain the blood values at a normal level. For this purpose, we submitted a patient, with a high index of infestation, to several doses of ferrous sulfate added to the food.

CASE REPORT

C. G., 22 years old, railroad worker, white, Brazilian, resident of Magé. Weight, 45 kilos. Admitted to the hospital on January 11, 1946. Discharged April 4, 1947.

Patient complains of extreme weakness, is easily tired, has dyspnea and palpitation after making the slightest physical effort. Can not say for certain when illness commenced, the symptoms appeared and progressed in unnoticeable manner. Says he had no venereal or rheumatic past. Although living in a malaria zone, informs never had malaria. Drinks alcohol in moderation.

General examination. Asthenic, badly nourished individual. Skin yellowed, visible mucosae highly discolored, almost white. Lesions of chronic scabies spread over trunk, abdomen, base of thighs, and hands. In the malar region on both sides and as far as the edges of the nose, symmetrical, irregular zones of dark coloring and a little shiny can be noted. On malleoli slight edema, less than one month old. No decrease or changes in appetite. Teeth are in poor condition. Tongue is white, broadened, and marks of teeth can be seen on tip.

Digestive system Epigastric region is sensitive to touch, but does not present spontaneous pain. No constipation, in last two months, attacks of diarrhea have been frequent. Liver and spleen not increased in volume.

Circulatory system Pulse light, soft, and rhythmic, with 84 pulse beats per minute. Blood pressure is 110/75. Lack of thrill in neck vessels. Ictus weak, located in fifth intercostal space, one centimeter inside the hemi-clavicular line. Systolic murmur (++) soft, audible at point and at base. Not spread by any focus. Diminishes in intensity at beginning of inspiration, and, on the other hand, increases when the individual lies down or when the auscultation point is pressed with stethoscope. In the pre-systole, the auricular sound is heard in the mesocardiac region. A₂ and P₂ are equal and normal.

Respiratory system and other systems, normal

Sequence in hospital The stay of the patient in the hospital was not apyrexial due to two factors not connected with the *Ancylostomiasis* (1) a secondary infection in some lesions of the scabies mentioned, (2) a dental abscess, both occurring when health conditions were very poor. With the use of iron, the symptoms and signs caused by the anemia diminished immediately. At the end of the first week, the

malleolar edema no longer existed. Urine examinations, made immediately after the patient was admitted to the hospital, and subsequent examinations, showed nothing to indicate that renal function was affected. Appetite was always good. The attacks of diarrhea disappeared. Forty days following beginning of treatment, the patient had gained 6 kilos weight. Color of skin and of mucosas practically normal, for our environment, at end of February, that is, 45 days after admittance. Tongue had regained tonus. Physical resistance permitted the practice of active exercise without reappearance of dyspnea and palpitations. Heart beat remained about 70 per minute. Blood pressure not changed, systole continuing between 105 and 115 and diastole at 75 mm Hg. Beginning the middle of March, systolic murmur no longer heard, only first sound found to be extended at point. Auricular sound heard only when the heart, because of the requirements of physical effort, became hyperactive. No opportunity to make radiologic study of this case.

We accompanied clinical course of the anemia with frequent electrocardiograms. We will analyze only two, spaced about three months apart. The others are transitional between these two, or repeat the second, which represents, so to speak, the final modification observed.

In figure 1 (January 16, 1946) and figure 2 (April 9, 1946), the second (fig 2) shows the following modifications when compared with the first.

- 1 Slight rotation of electric axis of the QRS to the left
- 2 Increased voltage on wave-length T in D₁ and in precordial positions left of the ictus,
- 3 Positivity of wave-length T in V₃

FIG 1

FIG 2

The electrocardiographic changes may partly be due to changes in the position of the heart. Increase of wave-length T in precordial positions left of the ictus in

Dr is probably due to changes of the process of repolarization of ventricular myocardium, caused by better nutritive conditions of muscular fibers

We started the therapy with iron, administering ferrous sulfate, 10 gram daily mixed with manioc flour, a food widely used in certain regions of Brazil. The blood values increased rapidly from 20 grams to 70 grams of hemoglobin per 100 cc of blood. We decreased the dose to 0.5 Gm daily, always added to the same food. At the end of two months, the hemoglobin value was practically normal (110 grams per 100 cc of blood). We then tried to determine the minimum dose necessary to maintain a relatively normal hemoglobin level. The administration of 0.1 Gm daily was insufficient to maintain this level, and hemoglobin decreased from 110 Gm to 80 Gm at the end of 110 days. Experiments with 0.2 Gm of ferrous sulfate, however, proved to be a sufficient dose to avoid the decrease, and enough

FIG 3

to keep the blood levels normal for 100 days. A graphic presentation of this observation is given in figure 3.

Attention should be called to the extreme clinical changes which occurred in this patient after iron was administered. When he was hospitalized, the patient was entirely apathetic, without strength to move, remaining in bed for a considerable portion of the day. As the blood values became normal, his functional activity was restored. In the final period of treatment, he remained semi-hospitalized, and worked in our laboratory. In carrying out his work, he walked daily about two kilometers from the hospital to the place of work. He became quite active, as can be seen by the fact that several times a day he went to the animal house, about 200 meters away, going up a steep incline and climbing three flights of stairs on returning to the laboratory. He no longer felt the symptoms of which he complained when he was hospitalized. He became, from all points of view, a perfectly normal individual.

Eggs of *Necator* were counted periodically, for control of the biologic activity of the helminth and the persistence of the degree of infestation

At the end of the trial period, five vermifuges (carbon tetrachloride 1.8 ml + *Chenopodium* oil 0.6 ml) were administered at weekly intervals. Helminths to the number of 1051 were eliminated, representing one of the most heavily infested cases we have observed (infestation index = 24 helminths per kilo of body weight). The fact should be kept in mind that the number of helminths eliminated represents a minimum, since it is easy to understand that not only do some escape at time of counting, but also others disappeared by natural death during the period of hospitalization.

SUMMARY

1 In individuals severely infested with *Ancylostoma* or *Necator*, it is possible to maintain the normality of blood value by the administration of a sufficient dose of an iron salt.

2 The minimum dose necessary to maintain normality of the blood in an individual weighing 45 kilograms, with 1051 helminths, was 0.2 Gm daily of ferrous sulfate, administered in mixture with manioc flour.

3 The patient observed became clinically normal two weeks after the beginning of blood regeneration up to the end of the trial period one year later. In this period, with the various doses of iron tried, hemoglobin varied from 8.0 to 11.0 per 100 ml of blood.

ACKNOWLEDGMENT

We owe thanks to the kindness of our colleague, Dr Genard Nobrega, for the case report and electrocardiographic study of the patient.

A STUDY OF SICKLING OF YOUNG ERYTHROCYTES IN SICKLE CELL ANEMIA

By JANET WATSON, M D

THE COMPARATIVE scarcity of sickled reticulocytes and normoblasts in patients with active sickle cell disease has been sufficiently striking to arouse comment by several students of that disease ^{1 1a 2 3} This observation led Murphy and Shapiro³ to postulate that the occurrence of hemolytic crises might be due in part to the increasing tendency of the red cells to sickle on aging, in which case the reticulocytosis of a crisis might of itself be beneficial The fact that their patient showed a higher percentage of sickle cells in the plain smear before crises than afterwards seemed to lend further support to this theory In reviewing many blood smears of sickle cell patients, I was able to find only two normoblasts and one reticulocyte in the sickled form A quantitative study of the sickling of reticulocytes was therefore undertaken

MATERIAL

Three patients with active sickle cell anemia from the Hematology Clinic of Kings County Hospital were chosen for study because they consistently showed a high percentage of reticulocytes and sickle cells in their blood The Wintrobe oxalate mixture was used as an anticoagulant for the venous blood obtained

METHODS AND RESULTS

1. *Sealed Preparation*

(a) *Blood* Oxalated blood was mixed with equal parts of 0.5 per cent brilliant cresyl blue in 0.85 per cent NaCl solution One drop of the mixture was used to make the standard slide-cover slip preparation This was sealed with paraffin, incubated at 37°C, and examined for sickling at frequent intervals In all cases sickling was complete within two to four hours This included the reticulocytes as well as the occasional normoblasts present It was the impression that most of the reticulocytes sickled as soon as the mature red cells, with the exception of some of the most immature reticulocytes which were packed full of reticulum The normoblasts appeared to be the last to sickle The progressive sickling of the reticulocytes could not be counted accurately by this method, however, because of the irregularity of sickling in different parts of the same preparation This irregularity has been mentioned by others, and is probably largely due to uneven distribution of the leukocytes, which have an accelerating effect on the sickling of the red blood cells,^{4 5} presumably through lowering oxygen tension by metabolism Platelet distribution may also be a factor ⁶

(b) *Bone Marrow* One cc of sternal marrow was obtained from one patient (W. B.) The buffy layer was used in a sealed preparation, made as described above, in order to study the sickling of normoblasts Cresyl blue stains the cytoplasm of the basophilic and polychromatophilic normoblasts, but not that of the orthochromatic normoblasts unless it happens to be reticulated The reticular network is easily distinguished from the diffuse blue staining of the basophilic normoblasts It was found that none of the basophilic and polychromatophilic normoblasts were sickled after 24 hours incubation at 37°C, whereas most of the orthochromatic normoblasts were in the sickled state Two of the latter type containing Howell-Jolly bodies, however, failed to sickle Since the orthochromatic normoblasts have a full quota of hemoglobin in their cytoplasm, their ability to sickle is not surprising Further evidence for the primary role of hemoglobin in sickling has been presented recently by Ponder,⁷ who showed that when meniscocytes were made into ghosts by lysis of their hemoglobin, they lost their ability to sickle

2. *Gas Chamber Method*

The apparatus used was essentially that described by Hahn and Gillespie⁸ except that the chamber was made of paraffin instead of glass. A water sealed outlet was found necessary.⁴ Both carbon dioxide and nitrogen were used for sickling. The same saline cresyl blue blood mixture was used. Since the red cells in the hanging drop can be studied directly with the oil immersion lens, this method has the advantage that the active dynamic process of sickling can be watched easily. Here again most of the reticulocytes seemed to sickle as fast as the other red cells, but the great rapidity of the sickling—about two minutes for complete sickling—made impossible the quantitative timing of the transformation of the two types of cells. Rarely would the rearrangement of the hemoglobin in the process of sickling result in the reticulum being lost from view. Occasionally the formation of the Sherman 'holly wreath' forms of sickle cells⁴ made this method, as well as that of the sealed preparation, unsatisfactory. Because of these disadvantages a chamber method which would permit slower sickling and the periodic removal of cells for counting purposes was devised as follows.

3. *Gas Test Tube Method*

A test tube, 15 x 40 mm, with a capacity of 5 cc. was set up with a gas inflow and outflow via 24 gage needles through a rubber stopper. The outflow was equipped with a water seal. Carbon dioxide was used

for sickling. One cc. of the saline cresyl blue blood mixture was introduced into the inverted test tube. Small samples of blood were removed at appropriate intervals under oil with an oiled tuberculin syringe and a 22-gage needle through the rubber stopper. The blood was immediately injected into formalin for fixation. Reticulocyte and sickle cell counts had to be done immediately in order to avoid inaccuracy due to slow fading of the reticulum in formalin. A 2 per cent formalin solution in normal saline was found to be as good a fixative as the standard 10 per cent solution and had less of a fading effect. A drop of the red cell suspension was placed on a slide under a cover slip, and a count was made under oil immersion of the reticulocytes and sickle cells. Only 200 cells were counted because of the time factor of fading.

The data obtained are shown in table 1. The number of sickled reticulocytes found per 100 RBC was divided by the number of reticulocytes per 100 RBC in order to calculate the percentage of sickled reticulocytes in terms of total reticulo-

cytes By comparing these figures with those for the percentage of total sickled cells, it is evident that the rate of sickling of the reticulocytes is quite similar to the rate of sickling of the whole red cell population A reticulocyte in the sickled form is shown in figure 1

A possible theoretic objection to the fact that sickle cells are not reticulated in an ordinary smear is that the abnormal shape interferes with the supravital staining In answer to this objection, blood was completely sickled in the test tube chamber, after which an equal amount of saline cresyl blue, previously aerated with carbon dioxide, was introduced into the test tube under oil The blood was examined after two minutes, and the sickled reticulocytes were found to be well stained

FIG 1

FIG 2

FIGURE 1 Meniscocytes sickled by carbon dioxide, stained with cresyl blue and immediately counterstained with Wright's stain Cells are shown in the process of unsickling with transition forms from the sickled shape to the biconcave disk Note the sickled reticulocyte at the left Two crescent forms have developed elongated processes at the ends The black spots with refractile contours are artefacts in photography

FIGURE 2 Peripheral blood smear stained with cresyl blue and Wright's stain Three reticulocytes and seven crescent, elliptical and oval shaped sickle cells can be seen None of the sickle cells are reticulated These sickled cells lack the bizarre shapes seen in Fig 1

In all three methods used, sickling of all erythrocytes and normoblasts was quickly reversible within a few seconds upon admission of oxygen to the system

DISCUSSION

Direct counting of the progressive sickling of reticulocytes on aeration with carbon dioxide (table 1) by means of a gas test tube chamber has shown that most reticulocytes sickle as well as the more mature cells However, it was noted in this and in the other methods used that the reticulocytes with the largest amount of reticulum were usually late in sickling The few normoblasts observed were also somewhat slow Although this may be due to the possibility that the most immature cells have a lower oxygen tension threshold for sickling, there is an al-

ternative explanation that the presence of a nucleus or of a large quantity of stain reticulum may mechanically interfere with the sickling process

The virtual absence of reticulated sickle cells in the ordinary smear (fig. 2) seems paradoxical at first glance. The sickle cells seen in the fixed blood smear appear different from the ones produced by *in vitro* sickling.^{2, 6, 9} The former are crescent shaped, elliptic, or oval and do not have the long processes seen in sickled preparations. When viewed directly in a hanging drop, these forms are seen to send out one or more elongated processes at the pointed ends on aeration with carbon dioxide, nitrogen, and to revert to their original shape on aeration with oxygen without going on to the normal discoid forms. For this reason these abortive sickle cells should perhaps have a distinctive terminology. It may be that they are old cells that have lost their "elasticity" from being kept in the sickled shape for long periods of time in stagnant blood vessels. Good evidence for the role of stagnation is presented by Diggs and Bibb² who had three patients with sickle cell anemia who had irreversible sickle cells in their pleural or ascitic fluid, although they had none in their stained blood smears. It should be possible to produce these crescent forms *in vitro* by keeping cells in their sickled shape for long periods of time, but attempts so far have been unsuccessful.* It is a well known fact that sickle cells are not seen in the blood smears of persons with the sickle cell trait. This could be predicted since the oxygen tension necessary for *in vitro* sickling (18 mm Hg)⁴ would never occur *in vivo*.

Reticulocytes, being young cells, may have more "elasticity," so that they are not fixed in the sickled shape *in vivo*. Or it may be that the length of time for stagnation of erythrocytes to produce these abnormal forms may surpass the estimated five to six day life span of the reticulocyte.¹⁰ If we accept Tomlinson's finding¹¹ that sickled cells are actually stuck in the interstices of the spleen pulp and cannot be perfused out, it would seem that the spleen could be an important dragnet of sickled erythrocytes in those patients in whom that organ had not become entirely fibrotic.

There is disagreement as to whether the number of circulating sickle cells differs from time to time in the same patient. Diggs and Bibb² and Smith¹² found little variation, while Sydenstricker¹³ and Murphy and Shapiro³ found that the sickle cells increased before the crisis and fell after the onset. Emmel¹⁴ also noted significant variation in his patient. The high viscosity of sickled cells¹⁵ and their abnormal shape tend toward their sequestration in organs, so that there could be an increasing accumulation of sickled forms without this increase necessarily being reflected in the peripheral blood. If this is so, the diverse reports among various investigators is not surprising. The increased mechanical fragility of the sickled cells^{2, 16} must be an important factor in their final demolition. Thus, a crisis results in the destruction of the old sickled cells and in the outpouring of new young red cells. Although the reticulocytes appear to sickle as well as other cells, they are

* A personal communication from Dr. Shu Chu Shen indicates that sterile incubation *in vitro* of erythrocytes maintained in the sickled form renders them unable to reassume the discoid form upon exposure to oxygen. The technic employed was the sterile incubation of defibrinated blood samples from either anemic patients or those showing the trait for only twenty-four hours. This incubation was carried out after preliminary equilibration with and during continuous exposure to a gas mixture composed of 90 per cent nitrogen and 10 per cent carbon dioxide.

not found in the irreversibly sickled shape. As the maturing red cell stagnates in anoxic organs, irreversible sickle forms appear, and augment the vicious cycle of stagnation, anoxemia, increasing sickling, thrombosis, and hemolysis.

SUMMARY

1 Data have been presented to show that most reticulocytes from patients with the sickle cell trait or sickle cell anemia sickle as readily as do more mature red blood cells. The most immature reticulocytes and normoblasts tend to sickle more slowly.

2 Orthochromatic normoblasts were the only type of normoblasts which sickled, the basophilic and polychromatophilic types could not be sickled.

3 It is suggested that the sickle cell forms seen in ordinary stained smears represent old cells which have lost their "elasticity" while stagnating in the sickle shape, and are unable to revert to a biconcave disk. This would explain the fact that these forms are so rarely found to be reticulated when stained with brilliant cresyl blue.

ACKNOWLEDGMENT

I wish to express my gratitude to Dr. William B. Castle, Dr. William Dock (Department of Medicine) for many stimulating suggestions, to Dr. John M. Pearce (Department of Pathology) for assistance in preparing this report and to Mrs. Muriel MacDowell (Department of Pathology) for the photomicrography.

Progress in Clinical Medicine

Written by twelve expert clinicians
Edited by **Raymond Daley, M.D.**,
Thomas' Hospital and **Henry G. Miller
M.D.**, Royal Victoria Hospital, Newcastle
on-Tyne

In its plan and presentation, the new book is particularly useful and dependable.

PROGRESS links your practice with the clinical achievements that have proved their worth.

In thirteen chapters the authors report on the advances in all the important medical fields. They are specific, critical and helpful.

The information is set down briefly and clearly. Drawings, photographs and x-ray pictures, amplify the text.

MICRO-ANALYSIS IN MEDICAL BIOCHEMISTRY

By **E J KING, M A**, Ph D, Professor of Chemical Pathology,
University of London

This manual of micro analysis was written by one of the leading workers in the field. Dr King is known especially for the development of procedures for blood analysis. He describes many improved and many new micro-methods for blood constituents.

Procedures for the analysis of cerebro-spinal fluid, faeces, urine, calculi, gastric contents, pH are presented. Spectroscopic procedures, tests of function, volumetric solutions, colorimetric and photometric measurements are taken up in the final chapters.

THE CHEMICAL SPECIFICITY OF THE INTERACTION OF DIVERSE HUMAN PLASMA PROTEINS

By EDWIN J COHN, PH D

RECOGNITION of the specific chemical functions of the various protein components of the plasma began in the eighteenth century. In his book, 'An Experimental Inquiry into the Properties of the Blood,' published in 1771, Hewson (fig 1) described the separation of fibrinogen from plasma.¹

When fresh blood is received into a bason, and suffered to rest, in a few minutes it jellies, or coagulates, and soon after separates into two parts, distinguished by the names of *Crassamentum* and *Serum*.

It is well known, that the *crassamentum* consists of two parts, of which one gives it solidity, and is by some called the fibrous part of the blood, or the *gluten*, but by others with more propriety termed the *coagulable lymph*, and of another, which gives the red colour to the blood, and is called the *red globules*. These two parts can be separated by washing the *crassamentum* in water, the red particles dissolving in the water, whilst the coagulable lymph remains solid. That it is the coagulable lymph, which, by its becoming solid, gives firmness to the *crassamentum*, is proved by agitating fresh blood with a stick, so as to collect this substance on the stick, in which case the rest of the blood remains fluid*.

*It may be proper to mention here, that till of late the coagulable lymph has been confounded with the serum of the blood, which contains a substance that is likewise coagulable. But in these papers, by the *lymph*, is always meant that part of the blood which jellies, or becomes solid spontaneously when blood is received into a bason, which the coagulable matter that is dissolved in the serum does not, but agrees more with the white of an egg, in remaining fluid when exposed to the air, and coagulating when exposed to heat, or when mixed with ardent spirits, or some other chemical substances.

Hewson thus recognized the water-soluble constituent of the red globules, the fibrinogen of the *crassamentum* or clot, and the coagulable proteins, largely the albumins, of the serum. Serum proteins, insoluble in water at a slightly acid reaction but dissolved by salt, were recognized by Denis and Scherer in 1841.² Over a century ago, therefore, the chief protein component of the red cells and at least three protein components of plasma had been recognized.

We now know that the pigment of the red globules, largely responsible for the respiratory function of the blood, is the prosthetic group of the protein, hemoglobin, and that the red blood cells contain in addition a large number of recently discovered protein components, among them carbonic anhydrase, catalase, phosphatase, choline esterase, hypertensinase and other peptidases. In this communica-

This paper is Number 63 in the series 'Studies on Plasma Proteins' from the Harvard Medical School, Boston, Massachusetts, on products developed by the Department of Physical Chemistry from blood collected by the American Red Cross.

It is well known, that the *crassamentum* consists of two parts, of which one gives it solidity, and is by some called the fibrous part of the blood, or the *gluten*, but by others with more propriety termed the *coagulable lymph*; and of another, which gives the red colour to the blood, and is called the *red globules*. These two parts can be separated by washing the *crassamentum* in water, the red particles dissolving in the water, whilst the coagulable lymph remains solid. That it is the coagulable lymph, which, by its becoming solid, gives firmness to the *crassamentum*, is proved by agitating fresh blood with a stick, so as to collect this substance on the stick, in which case the rest of the blood remains fluid*.

• It may be proper to mention here, that till of late the coagulable lymph has been confounded with the serum of the blood, which contains a substance that is likewise coagulable. But in these papers, by the *lymph*, is always meant that part of the blood which jellies, or becomes solid spontaneously when blood is received into a basin, which the coagulable matter that is dissolved in the serum does not, but agrees more with the white of an egg, in remaining fluid when exposed to the air, and coagulating when exposed to heat, or when mixed with ardent spirits, or some other chemical substances.

WILLIAM HEWSON

(1739-1774)

AN EXPERIMENTAL INQUIRY

INTO THE

PROPERTIES OF THE BLOOD.

P R E F A C E.

THE knowledge of the human frame, the preservation of health, and the cure of diseases, are objects of too great importance to mankind, for the Author of these sheets to doubt, that any attempts to promote them, how small soever, should not meet with a candid and indulgent reception from the public. An Inquiry into the Properties of the Blood, it is presumed, will be thought, in a particular manner, interesting, since there is no part of the human body upon which more physiological reasoning is found-

ed,

The Preface of Hewson's work

An Experimental Inquiry into the Properties of the Blood

of the blood with which it is mixed

of the blood with which it is mixed

tion we shall concern ourselves, however, with the plasma proteins and the specific chemical reactions upon which their physiologic functions depend

The relation of fibrinogen to the clotting of the blood was implicit in Hewson's discovery. Although Hewson found ways of blocking fibrin formation it remained for Andrew Buchanan to demonstrate, in 1845, 'that fibrin has not the least tendency to deposit itself spontaneously in the form of a coagulum that like albumen and casein, fibrin only coagulates under the influence of suitable reagents and that the blood, and most other liquids of the body which appear to coagulate spontaneously, only do so, in consequence of their containing at once fibrin and substances capable of reacting upon it, and so occasioning coagulation' ³ The substance which Buchanan noted, by virtue of its physiologic action, was presumably thrombin. Satisfactory studies upon thrombin as a globulin, were, however, not carried out until this century ⁴⁻⁹

Meanwhile albumins and other globulins had been noted in terms of chemical properties, often however, without these properties being associated with specific biologic functions. The chemical studies which have continued during the last century have yielded relatively pure preparations of albumins and demonstrated that there were many kinds of globulins.

Molecular Dimensions of Plasma Proteins Although there is evidence of more than one albumin ¹⁰⁻¹⁵ all serum albumins which have been studied thus far, of human or animal origin, have closely similar molecular properties, isoelectric points near pH 4.9, molecular weights near 70,000 and molecular dimensions described as ellipsoids 150 Ångströms in length and 38 Ångströms in width. All plasma proteins thus far investigated have diameters of this magnitude or greater. If the smallest dimension is less, the molecule appears not to be retained in the blood stream, but to be lost through the kidney. Among molecules of the same diameter, where loss occurs it appears to be inversely related to the length of the molecule. This should apply not only to rod-shaped molecules of diameters of the order of 20 Ångströms or less, ^{* 16} but also to the plasma proteins under pathologic conditions. Among plasma proteins with roughly the same diameter, of 38 Ångströms, the β_1 -globulins which combine and transport copper and iron, have been estimated to have a length of 190 Ångströms, the γ -globulins, concerned with immunity, of 235 Ångströms, and fibrinogen, concerned with blood coagulation, of 700 Ångströms ¹⁷

The viscosity of proteins depends, of course, not upon their size but upon their asymmetry. Thus fibrinogen, the most asymmetrical of the plasma proteins has an intrinsic viscosity six times that of albumin. Were it present in the plasma in large amounts, instead of to but 4 per cent, it would impose considerable burden upon the circulation. Serum albumin is far more symmetrical, a 25 per cent solution being isoviscous with blood ^{18, 19}

The albumins are, moreover, the most stable, the smallest and the most copious of the plasma proteins. Present in normal plasma to just over 50 per cent they are responsible for nearly 80 per cent of the colloid osmotic pressure which regulates the equilibrium in water and electrolytes between the plasma and the tissues, and

^{*} Characteristic of the various suggested blood substitutes which were examined but not recommended to the Armed Forces.

thus play the major role in maintaining the volume of the blood upon which normal circulation depends^{16 20}

The molecular size and shape of proteins, once they are separated as homogeneous chemical components, may be estimated by measurements of osmotic pressure and of viscosity. The ultracentrifuge renders it possible, however, to distinguish proteins of different molecular dimensions even in so complex a mixture as plasma. The constant defining the speed of motion of a protein in the field of the ultracentrifuge, for the development of which we are indebted to Svedberg,²¹ has revealed proteins sedimenting in plasma with four very different velocities²²⁻²⁴. Those sedimenting with the smallest velocity include the albumins and certain globulins. The other globulins which have been separated and fibrinogen sediment with other velocities. However, ultracentrifugal analysis does not permit us to distinguish a large number of components in the plasma.

Electrophoretic Mobilities of Plasma Proteins Solubility studies during the nineteenth century indicated that there were many globulins and classified them as euglobulin or pseudoglobulin, depending upon their insolubility or solubility, in the absence of salt, or in concentrated salt solutions. Electrophoretic analysis, refined by Tiselius, distinguished globulins in terms of their mobility in an electric field and designated them α -, β -, and γ -globulins²⁵⁻²⁷. Better resolution by the optical system employed in the analysis has revealed more than one α -, more than one β -, and more than one γ -globulin. Two α -globulins, α_1 and α_2 -, two β -globulins, β_1 - and β_2 -, and two γ -globulins, γ_1 - and γ_2 -, the second one, in animals, sometimes termed a T-globulin, are now often designated. If we include the results of electrophoretic analyses the number of protein components of plasma recognized by physico-chemical means has thus increased to nine or more from the three recognized a century ago.

Hormones A very large number of protein components of the plasma has been postulated on the basis of physiologic or immunologic properties. Some of these have been concentrated and characterized. Others, like the hormones, by definition components of the blood, have rarely been separated from it, or even detected in it.

Immunoproteins Immunologic studies have led to the recognition and the study of complement and its components²⁸⁻³⁰ and of a variety of antibodies.³¹ Antibodies have been characterized, as euglobulins and as pseudoglobulins, in terms of their solubilities. Many, but not all, antibodies have been characterized as γ -globulins in terms of their electrophoretic mobilities. Among γ -globulins some have been described of very high molecular weight, others of molecular weights of the order of 156,000. For the most part, however, these immuno-chemical studies have not led to the isolation of pure antibodies of which there could conceivably be as many as the antigens which have led to the production by the body of specific antibodies.

Enzymes Prothrombin is presumably present in the body in but small amount and the action of thrombin is now generally regarded as enzymatic. The presence of a large number of other enzymes has since been demonstrated by virtue of their specific interactions. Thus there is the proteolytic, fibrinolytic, enzyme now called plasmin, a well-defined serum esterase, two phosphatases, a lipase, an amylase, and a number of peptidases, among them hypertensinase. Most of these substances

are far better known in terms of their chemical interactions than of their molecular properties

Lipoproteins Recent investigations have demonstrated the presence of different lipoproteins in the plasma, moving in the electric field respectively with the mobilities of α_1 - and β_1 -globulins. One of these lipoproteins is an asymmetric molecule with a molecular weight of roughly 200,000. Another is a large spherical lipoprotein with a molecular weight of over a million.¹⁷ These lipoproteins are noteworthy both because of their physical properties and because they render soluble such water-insoluble lipids as cholesterol, carotene and the steroids and because the specificity of their interactions is such that one of the estrogen hormones, estriol, has been found to be combined not with all, but only with one of these lipoproteins, the large spherical β_1 -lipoprotein.³²

Albumins Until recently the greatest emphasis has been upon the osmotic function of the albumins in maintaining the equilibrium between water and electrolytes in the blood and in the tissues. The development of normal human serum albumin for use in military medicine, for the treatment of shock, burns and hypoproteinemia, depended upon the molecular properties of albumin. However, as Bennhold³³ and later investigators³⁴ suggested, albumins interact with a variety of smaller molecules, notably with nonpolar anions such as aliphatic fatty acids³⁵⁻³⁷ and are presumably responsible for their transport in the blood stream. Albumins also interact with a variety of dyes³³ including Evan's blue, often used in estimating blood volume³⁸ with naphthoquinones such as those developed as antimalarials³⁹ and with a variety of other dyes.⁴⁰⁻⁴² Albumins also combine with a variety of drugs, such as atabrin, neosalvarsan,³³ and digitoxin,⁴³ mercurials⁴⁴ and sulfa drugs.^{45, 46}

Crystallized Human Serum Albumins Not all of the properties that have been ascribed to the albumins are due to these molecules. In order to demonstrate this, it was necessary to prepare highly purified crystallized human serum albumins.⁴⁷

Human serum albumins that had been crystallized by earlier methods were demonstrated to contain over 2 per cent of long chain fatty acid.⁴⁸ The albumins that we have crystallized, in very satisfactory yield, from alcohol-water mixtures of defined pH and ionic strength at low temperatures also contained fatty acid, but the amounts present were far smaller, of the order of one mole stearic or oleic acid per mole of albumin. The fatty acid appeared to form an integral part of the crystal structure and, in fact, crystallization appears to be greatly aided by the presence of such amounts of fatty acid and by the addition of higher alcohols such as n-decanol. The amounts of the alcohol that have been found useful and with which the albumins combine range from two to ten moles per mole. Crystallized with the aid of such reagents, albumins can be recrystallized under a variety of physical chemical conditions and in a variety of crystal forms.

The resolution of the various albumins that crystallize together required a more specific method of crystallization in order to yield chemical individuals. Conditions for crystallizing horse serum albumin of constant solubility had been determined in our laboratory before the war by McMeekin.⁴⁹ This method has thus far not been found effective for crystallizing a fraction of human serum albumin. However

a large fraction of the human serum albumins crystallized by the decanol method has been found by W. L. Hughes, Jr., to form a relatively insoluble crystalline mercury compound.⁵⁰ The albumin separated in this way appears to be a chemical individual whose solubility behavior approximates to that of a simple chemical substance.

Although serum albumins combine with a larger number of equivalents of mercury the amount with the albumin in the solid phase of crystals precipitated in this way is but one-half a mole of mercury per mole albumin. That is to say, each mole of mercury appears to be combined with two albumin molecules in the solid state.⁵⁰ In solution, however, this complex dissociates. Albumin of double molecular weight has been detected in the ultracentrifuge and reconverted to normal size either by the removal, or the addition of larger amounts, of mercury.

Pigment Proteins Serum albumin had previously been reported to combine with hematin and with bilirubin.⁵¹ Upon adequate recrystallization, the amount of both diminish until they can no longer be readily detected spectrophotometrically. Upon equilibrating such pure serum albumin with these substances, however, combination can be demonstrated and quantitatively estimated. Albumin which we have recrystallized has been studied in equilibrium with hematin⁵¹ and with bilirubin.⁵² At alkaline reaction albumin combines with as much as three moles bilirubin per mole albumin. At acid reactions, however, the bilirubin is free and can be removed by dialysis.

Bilirubin is also a component of a true pigment protein of the blood stream, normally present to less than a tenth of a per cent of the plasma proteins. This bilirubin pigment protein interacts strongly and is, therefore, separated with difficulty from the 50 per cent of albumin in plasma. It has now been separated, however, and alone of adequately purified plasma proteins, gives the indirect van den Bergh reaction.⁵³ Another pigment protein responsible for a very characteristic blue-green color does not give this reaction and although often found associated with crude albumin preparations is a globulin concentrated in our system of fractionation in Fraction IV-1, whereas the yellow pigment, due to bilirubin, is concentrated in Fraction V-1.

Iodoproteins Iodine combines with essentially all proteins, entering the phenol ring to form diiodotyrosine and also entering the imidazol ring. Albumin rich in iodine has been prepared and crystallized by Salter from horse serum.⁵⁴ In studying the distribution of iodine in the human plasma fractions that we have separated some has always been found with the albumin, some however, has been found in Fraction IV-6. The further study of the iodoprotein in these fractions should reveal more regarding the nature of the plasma molecules of which it is a part.

Metal-Combining Proteins It has long been known that copper, iron and zinc are combined by plasma protein. The separation of the plasma proteins into fractions in which are concentrated the molecules responsible for specific interactions has yielded, in Fraction IV-7, the β_1 -globulin responsible for the combination and transport of copper and iron and perhaps of zinc in the plasma. The close interrelation of the copper and iron in plasma had been noted in clinical studies.⁵⁵⁻⁵⁷ The combination of a component of plasma with iron was noted in connection with

TABLE 1 Protein Composition of Human Plasma Separated and Concentrated in Diverse Fractions

* These components represent but small proportions of the fraction and subfraction, and their properties cannot, therefore, be deduced from those of the concentrates in which they have been separated.

† These components have not been tested for since revision of the fractionation process.

‡ Albumin binds more bilirubin than the bilirubin pigment globulin in Fraction V 1 and more iodine than has been found in Fraction IV-6.

§ When purified chemical components have been separated from fractions they have not been given new fraction numbers. In that case, the fraction number refers to the starting material for the separation of the component.

bacterial studies⁵⁸ and has led to its identification in a plasma fraction, to its further purification and characterization, and recently to its crystallization in collaboration with Bernhard A. Koechlin,⁵⁹⁻⁶¹ in our laboratory. Physiologic studies of the role of the separated protein injected into man have begun⁶²⁻⁶⁴ with a view to determining its function and possible value in therapy.

Specificity of Chemical Interactions. The multivariable method for the fractionation of plasma that we have developed not only separates protein components in terms of their molecular properties, but also in terms of the very specific chemical configurations upon which their interactions depend. Insofar as the system of fractionation is successful each protein component responsible for a specific chemical reaction and physiological function is separated from those of different properties and concentrated. Thus one fraction should be positive with respect to any test to which the whole plasma is positive, all others should be negative. The extent

to which this end has been accomplished may be demonstrated by the following studies upon protein interactions.*

1. Interaction of Naphthaquinone (M1523†) Caprylate and Serum Proteins

Solutions

Five per cent solutions of the following proteins are used. Volume of each is 10 ml.

γ -Globulin (Fraction II) in acetate buffer pH 7.5-1.2 = 0.05

β_2 -Globulin (Fraction IV-7) =

Albumin (Fraction V) =

Albumin (Fraction V) in caprylate =

An acetate buffer blank =

Albumin control in acetate buffer as above but with naphthoquinone added at the advance of the demonstration time

Reagent

Naphthaquinone, M1523‡

Method of Demonstration

To beakers containing each of the above solutions a small amount of naphthaquinone is added, stirred, and let stand 10-20 minutes. A beautiful red color develops in the solution containing acetate, but is blocked in the albumin solution. Control albumin solutions and blank give fainter colors.

2. Block of Bile Salts by Serum Proteins

Solutions

Serum Albumin, 2.5 per cent solution

Reagents

Bile Salts, 2 per cent solution

Red cells as an indicator

0.15 M sodium chloride solution

3 *Binding of Copper and Iron by β_1 -Globulin (Fraction IV-7)**Solutions*

2 per cent solutions of the following proteins are used Volume of each solution, 300 cc

Fibrinogen (Fraction I)	} All are dissolved in pH 8.5† $\Gamma/2 = 0.05$ barbiturate buffer
γ -Globulin (Fraction II)	
β_1 -Globulin (Fraction IV-7)	
Albumin (Fraction V)	
β_1 -Globulin (Fraction IV-7) control*	

Reagents

1 $\text{CuSO}_4 \cdot 5 \text{H}_2\text{O}$

Four bottles each containing 0.027 Gm $\text{CuSO}_4 \cdot 5 \text{H}_2\text{O}$ dissolved in 20 cc H_2O

2 $\text{FeSO}_4 (\text{NH}_4)_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$

Four bottles each containing 0.048 Gm $\text{FeSO}_4 (\text{NH}_4)_2\text{SO}_4 \cdot 6 \text{H}_2\text{O}$ dissolved in 20 cc 0.001 M acetic acid

3 One bottle containing 27 cc 1 M acetic acid

4 One bottle containing 27 cc 1 M NaOH

Method of Demonstration

All solutions must be stirred during addition of reagents

1 *Copper Binding*

Add copper solution to all protein solutions β_1 -Globulin is the only protein solution that will give a positive reaction. A yellow-green color develops in 3-5 minutes pH is about 8-8.2

2 *Iron Binding*

Add iron solution to all protein solutions β_1 -Globulin again gives the only positive reaction. A red color develops in 3-5 minutes as the copper is replaced by the iron pH is about 8-8.1

3 *Splitting Iron off the Protein†*

Add the acetic acid. The protein solution regains its original appearance pH is about 4.3

4 *Recombining the Iron*

Add the sodium hydroxide. The red color reappears pH is about 8-8.1

Note The yellow-green color of the copper and the red color of the iron become somewhat more intense with time

4 *Modified van den Bergh Reaction⁵³ for Identification of Bilirubin**Solutions*

1 per cent solutions of the following plasma fractions are used Volume of each, 120 cc

Fraction II

Fraction IV-2

Fraction IV-7

Albumin

Fraction V-1-B

} All solutions are made up in pH = 8.6, $\Gamma/2 = 0.025$ §barbiturate buffer

* The reagents listed below are added to the control about 4-6 hours in advance of the demonstration time

† This pH is lowered slightly upon the addition of the copper and iron salts, due to acidity of the salts themselves, and because 0.001 M acetic acid is used to dissolve the $\text{FeSO}_4 (\text{NH}_4)_2\text{SO}_4 \cdot 6 \text{H}_2\text{O}$

‡ It is necessary only to add acid and base to the β_1 -Globulin solution since it alone gives a positive reaction to the iron

§ The ionic strength of Fraction II is adjusted to 0.04 with 1 M NaCl to keep it from precipitating on addition of reagents. If higher ionic strength for IV-2 and V-1-B is used, they will precipitate on adding reagents

Reagents

- 1 Solution A
- 1 g Sulfanilic acid dissolved in 15 cc concentrated HCl and diluted to 1 liter with water
- 2 Solution B
- 0.5 per cent NaNO₂
- 3 Diazo reagent prepared fresh by adding solution B to solution A in the following ratio 0.3 cc B to 10 cc A
- 4 Absolute methanol

The reaction mixture to be added to the protein solutions is prepared about an hour before the demonstration, as follows

Add 5.7 cc solution B to 190 cc solution A. Add 190 cc of this diazo reagent to 950 cc absolute methanol *

Method of Demonstration

Add 180 cc of the above reaction mixture to each of the protein solutions with vigorous stirring. A precipitate may form, but will redissolve.

The V-1-B solution will develop a pink color almost instantaneously. The other solutions give a negative reaction.

*5 Coarse and Fine Types of Fibrin Clots†**Solutions*

A 2 per cent solution of Fraction I is prepared for this demonstration.

Note The Fraction I used is dried from the frozen state from a 2 per cent isotonic solution in sodium citrate, volume 300 cc and it is only necessary to add 300 cc distilled water to reconstitute it. pH = about 6.3-6.6.

After the Fraction I is dissolved it is clarified, by filtering successively through D-5 and D-5 Horman filter pads. These pads may be first washed with 0.1 M acetic acid, then with water to free them of acid.

After filtration the solution is divided into two 125 cc portions. One remains as it is at pH 6.3-6.6, the other is adjusted to about pH 8 by the addition of 18.8 cc 1 M NaHCO₃ solution.

Reagent

The only reagent necessary is a thrombin solution made by dissolving two small bottles of thrombin (about 500 units each) in 50 cc 0.15 M NaCl solution.

Note If this solution is cloudy it is clarified by filtration through a small D 5 Horman filter pad.

Method of Demonstration

Coarse Clot To the pH 6.3 portion of Fraction I, 12.5 cc thrombin solution are added and stirred quickly to mix the two solutions.

In about 5 minutes a clot forms firmly enough to permit inversion of the container. This clot is opaque.

Fine Clot To the pH 8 portion, 12.5 cc thrombin solution are added and stirred quickly.

In about 5 minutes or slightly longer, a firm clot forms, so that the container can be inverted. This clot is clear. *Note* This clot forms a little more slowly than the coarse clot.

SUMMARY

The chemical methods that have been developed for the separation, concentration and purification of the protein, glycoprotein, mucoprotein, and lipoprotein

* Reaction mixture should not develop a color. If a color develops it is probably due to an impurity in one of the reagents. Therefore fresh reagents should be prepared.

† This demonstration depends upon the experiments of J. D. Ferry and P. R. Morrison.

components of any biologic system, by fractionation in alcohol-water mixtures controlled pH, salt, and protein concentration, at the subzero temperatures necessary to prevent denaturation, have thus far led to the recognition and concentration of over twenty-five different protein components of human plasma. These include albumins of more than one kind, immune globulins which differ in their physical properties and interactions with antigens, lipoproteins which differ in their physical properties and interactions with steroids, enzymes with proteolytic, peptidase, lipase, phosphatase and esterase activity, thrombin, fibrinogen, and the antihemophilic globulin concerned with blood coagulation, iodoprotein and the recently crystallized metal-combining protein which interacts with both copper and iron and is presumably concerned with transport in the plasma.

This number of plasma proteins is far greater than can be detected electrophoretically or in the ultracentrifuge. Chemical fractionation has yielded at least four β_1 -globulins and at least two α_1 - and three α_2 -globulins. The α_2 -globulins include mucoprotein and glycoproteins of more than one kind, the α_1 -globulins, the bilirubin-containing globulin in Fraction V-1 and the lipoprotein in Fraction IV-1. The β_1 -globulins include the carotene-rich euglobulin which combines with three times its weight of lipid as well as a high molecular weight lipid-free β_1 -globulin, both of which are concentrated in Fraction III-o. Fraction III also contains β_1 -globulins of different molecular properties. The iron-binding component of the plasma, crystallized from fraction IV-7, is a lipid-free β_1 -globulin and is more closely related to the albumins than to other globulins from the point of view of osmotic activity. Electrophoretically indistinguishable, these different β_1 -globulins have no other common property. The lipid-binding plasma component is a β_1 -euglobulin, the iron-binding β_1 -component a pseudoglobulin. They differ in size, shape, in solubility, in chemical composition and interaction, and in physiological function.

The separation and concentration of the various proteins of human plasma was undertaken during this war in order to render as many as possible available as therapeutic agents and thus to increase our knowledge and control of the composition of the blood in health and in disease. Many more have been separated and are being studied chemically than have thus far been brought to clinical trial. Their study renders possible the further investigation of the chemical specificity of the interactions of the plasma proteins, which are responsible for many of the tests that have in the past, or may in the future, prove of value in the clinic in the study of pathological sera and the understanding of the specific protein component that is either elevated or deficient in this condition.

THE SPAN OF LIFE OF THE RED BLOOD CELL A RÉSUMÉ

By WINIFRED ASHBY, PH D

THE QUESTION of the life span of the red blood cell has been an open one for the past hundred years. Beginning with naive attempts to determine the duration of the corpuscle in the circulation by transfusions of foreign nucleated cells into the mammalian blood stream,¹ the quest continues as of November 1946 with the most modern biologic tool, the isotope, and with full benefit of higher mathematics in the analysis of the data collected. A solution at last seems to be in sight.

The fact that the mammalian red blood corpuscle is an incomplete cell, which has lost its nucleus, together with the fact that it is of necessity subjected to the stress of contortion as it passes through the capillaries, has made its ephemeral existence an acceptable hypothesis. To anyone who has had the privilege of seeing the beautiful moving picture made by Professor August Krogh showing the opening and contracting of the capillaries and of the red blood cells being crowded through them, it is amazing that the frail erythrocyte should survive for any great length of time.

Two schools of thought have arisen concerning this subject. One is influenced by the seeming fragility of the corpuscle irreconcilable with any long buffeting in the circulation. Its members still accept the earlier work upon the rate of bile pigment excretion which argues for a short life of the cell.² The chief protagonist of this school is Dr. Raphael Isaacs. His expressed opinion as of 1938 was as follows: "As the erythrocytes in mammals are non-nucleated it is evidently impossible for repair and metabolic nutrition to be a part of their normal physiology. Their life duration must be limited and is probably shorter than most of the fixed tissue cells, but the exact or even approximate length of service is not known."³ This opinion is still acceptable to many authorities in the field of blood physiology and has appeared in some of the postwar textbooks, in which the physiology of blood destruction is discussed. For instance, in "An Integrated Practice of Medicine"⁴ (1946), edited by Harold Thomas Hyman, we find the following statement on page 1038: "The life of the normal erythrocyte is very limited and probably does not exceed a span of more than six weeks."

The other school bases its judgment upon certain technics which tag the corpuscle, either directly or indirectly, and enable the observer to follow it until it is eliminated. The members of this school accept, notwithstanding its seeming improbability, a life span of approximately 120 days for the red cell in the normal body.

THE METABOLISM OF THE MAMMALIAN RED BLOOD CELL

Since this supposed frailty of the non-nucleated erythrocyte has played so great a part in our thinking concerning the span of life of the red blood cell it would

From St. Elizabeths Hospital, Washington, D. C.

seem well to examine the evidence which concerns the position, from the point of view of metabolism, which the red cell holds in the society of cells which compose the mammalian organism

In the first place, although the nucleus is necessary for cell division and reproduction, it is not necessary for the continued life of the cytoplasm. This has been beautifully demonstrated by Dr. Chambers, especially in his work upon the enucleated amoeba, which survives for a long time, forming contractile and gastric vacuoles. The nucleus is not, as one was inclined to think in one's high school days, the brain which directs the metabolic activities of the cell. The cytoplasm also has its enzymes by which its metabolic activities are accomplished. One thinks of the various components of the cell as being produced *in situ* from previous material of the same kind. For instance, botanists have long regarded the plastid, that component of the cytoplasm in which starch is produced when the leaf is illuminated, as being capable of reproducing itself and of passing on as such when cell division occurs.⁵ In the recent conference on the chemistry and physiology of growth held at Princeton, the question was proposed as to the passivity of the cytoplasm and attention was called to self-perpetuating cytoplasmic entities in lower forms which could be passed from the cytoplasm of one cell to another, dependent to some extent upon the genes of the host.⁶ In line with this are recent disclosures by way of the isotope. To quote Addison Gulick: "Studies with radioactive nitrogen have demonstrated that proteins in the living cell are constantly undergoing exchanges of their amino acid residues. Thus, even after it is completely synthesized, the protein molecule does not maintain its absolute identity of material, but merely a steady state with like configuration of like materials."⁷ The same author mentions the fact that the cytoplasm has its own nucleoprotein, which is different from the nucleoprotein of the nucleus, but is of the same type as that found in viruses, or at least in the tobacco virus. And the tobacco virus is not only capable of maintaining itself, but, given the cooperation of a suitable cell, of very extensively reproducing itself. Red cells are reported to contain nucleoproteins. They also contain catalysts such as phosphatase, carbonic anhydrase, coenzyme, choline esterase, catalase, urease, lipase. Barron⁸ quotes some work indicating that red cells can synthesize flavin adenine-dinucleotide from riboflavin *in vitro* and *in vivo*. It would seem then that the long cherished conception of the histologically minded hematologists that the red cell is a passive hemoglobin containing sac with little other content, will have to be modified.

We have several indirect points of evidence to the effect that the red cell may be able to repair itself. For instance, a small amount of glucose, the prime source of metabolic energy, aids in preventing deterioration of drawn blood. Maizels has shown that glucose inhibits the breakdown of organic phosphates in the stored cells.⁹ Maizels and Paterson showed that stored cells that had taken up sodium at the expense of their normal potassium, although they still possessed this excess after half an hour in the blood stream, lost it in twenty-four hours against the steep concentration gradient produced by the content of the patient's serum. They consider that the cells have been "reconditioned" in a more complex manner than would be accounted for by a simple physical process.¹⁰ There is also the loss of the

specific polysaccharides constituting the a and b antigens, which takes place when cells are stored under the stabilizing influence of a lowered temperature and removed from the strain of the circulation. Whereas under the stress of the circulation the high degree of agglutinability is maintained. This would suggest that in vivo the corpuscles have capacity to replace the loss of these specific polysaccharides.

The very low metabolism found by Warburg, at least in the corpuscles of man, is rather against the idea of the synthetic repair of the red cell in the blood stream, since energy is required for the building of protein and of the polysaccharides.¹¹ Ramsey and Warren find the respiratory rate of red cells to be comparable to the rate of other resting tissues ($30-70 \text{ mm}^3/\text{Gm/hr}$).¹² G. P. Wright finds that normal orthochromatic erythrocytes have a negligible respiration, if any, but that oxidation increases with increases in reticulocytes and is in proportion to their number present.¹³ Similar findings had previously been reported by Barer, Needle and Baldrige.¹⁴ The argument in favor of any metabolic repair in vivo would be in a bad way if it were not for the work of Harrop and Barron who showed that non-nucleated erythrocytes respire to an extent comparable to the respiration of other tissues in the presence of a hydrogen acceptor. They used methylene blue.¹⁵ Following this, Michaelis and Salmon found in aqueous extracts of the body tissues, notably the liver, something which acted in a manner similar to methylene blue and raised the respiratory rate of the red blood cells to the level of tissue cells.¹⁶ It would seem almost certain, then, that in vivo the metabolism of the red cell is such that the cell would have the energy necessary to repair its own deteriorations.

THE STUDY OF TRANSFUSIONS AND HEMORRHAGE

The first attempts to determine the life of the erythrocyte, that from the point of view of our present knowledge must be considered seriously, were the studies of transfusions or of hemorrhage using changes in the total blood count as the indicator. Hunter,¹⁷ in a report before the Royal Society of Edinburgh in 1885 of his own work in this line and of that which preceded his, gives the results obtained by Ward-Miller, Quinck, and von Ott. Ward-Miller transfused dogs and produced a plethora. After two or three days he judged that the number of corpuscles responded to the number transfused plus the original count. After a few weeks the count had returned to its first level. Hunter, in order to avoid the abnormal condition of plethora, injected blood intraperitoneally, von Ott removed large amounts of blood, injected defibrinated blood and observed the time taken for the total count to drop to a minimum. The period of observable change indicated by this work was between fourteen and twenty-six days.

Various modifications of the above type of experimentation have continued to date. In 1934, Escobar and Baldwin introduced a new factor in that they produced the plethora by exposure to low oxygen pressure.¹⁸ They also measured plasma volume. They did not count reticulocytes, which Rous and Robinson^{19, 20} found reduced to zero in their studies of increase in fragmented corpuscles produced with plethora. They did not allow the cell count to increase under oxygen need beyond a certain arbitrary amount because they said, "If the cell count is too great the

compensatory erythro-destroying mechanism begins to act and the supernumerary cells under observation may not live out their allotted normal life span." The results of these workers are in good agreement with other work in which this general method has been used. In rats the count returned to normal in from twelve to eighteen days, in the dog from sixteen to twenty-three days, in man from eighteen to thirty days.

In all of this work which deals with the whole blood there are three underlying factors, and probably a fourth, two of which are quantitatively indeterminate and therefore vitiate any quantitative results. The quantitatively indeterminate factors are blood destruction and blood production. In the reticulocyte count we have a qualitative index of blood production, but there is no way in which the number of reticulocytes can be interpreted in terms of the number of red cells that are being produced. The length of time that an increased count remains above normal could be taken as an index of the length of time that the cells producing this increased count remained in the circulation, only if we were certain that no change had taken place in the relative rate of production and destruction which maintained the original cell count. This we cannot assume. In fact, we have evidence in the work of Rous and Robertson²¹ that plethora causes a reduced production, as shown by absence of reticulocytes and by a reduction in the count of cells in the bone marrow, and also an increased destruction, as shown by the increase of schizocytes in the spleen. Both increased destruction and decreased production would cause the count to return to normal without the necessary destruction of the cells introduced to cause the excess counts, especially if the excess cells were the youngest cells in the community, as would be the case in the experiment of Escobar and Baldwin. The duration of the plethoric count would always be shorter than the life of the cells which produced it.

In 1930 Eaton and Damren made an interesting contribution to the problem.²² They subjected rabbits and dogs to fairly severe hemorrhage and studied the appearance of reticulocytes. The curve of their appearance showed marked crests which gradually subsided through five or six cycles. The interval between crests in the dogs' curves was approximately sixteen days and that of the rabbits eight and one-half days. They infer that the blood which is produced in the first crest is destroyed and its destruction is the stimulus for the second crest, and so forth.

These data would be strong evidence in favor of the shorter term of life of the red cell, if there were not some indication that activities of the organism do not proceed at a constant rate, but are subject to more or less regular fluctuations. From this point of view these data could be explained as magnifications of these tendencies to periodic increases in growth activity caused by the stimulus of increased need. This tendency to rhythmic fluctuations in the anabolic and catabolic activities of the organism, which appear to become more evident under stress, needs to be recognized clearly in attempting to evaluate the evidence concerning the length of life of the red cell.

Ashby in 1921 reported that "Group O corpuscles transfused into a recipient with agglutinable corpuscles disappeared in steplike intervals that might be from two to four weeks in span."²³ Wearn, Warren and Ames using the same techni-

failed to observe these abrupt changes, but they admitted that their observations may not have been sufficiently closely spaced to catch them ²⁴ Of course there are many rhythmic phenomena which have been studied in relation to the menstrual cycle, but there is also evidence that such rhythms occur independently They may be seen in weight curves in persons on a reducing diet The cross striations on the fingernails have been attributed to such fluctuations in growth Upon measuring the growth of a series of fingernails through several weeks, I have found such fluctuations at intervals of from twelve to fourteen days ²⁵ Schultz, in a study of fetal growth in man, states that the rates of growth of different parts of the body are frequently found to alternate during fetal life which indicates a certain fluctuation in the rate of growth " (p 391) ²⁶ One of the most careful studies of these fluctuations was made by Broun, McMaster and Rous ^{27 28} They used this phenomenon in their study of the relation between blood destruction and the output of bile pigment They describe it as slow, wavelike changes in hemoglobin content and bile pigment output with often as much as a fortnight elapsing between crest and crest If we are willing to accept the longer life of the red blood cell, then the findings of Eaton and Damren also become evidence for a periodicity in the activity of the hemopoietic system

BILE PIGMENT METABOLISM AND THE SPAN OF LIFE OF THE RED BLOOD CELL

Since bile pigment is derived from hemoglobin it is inevitable that measurements of bile pigment excretion will have played a large role in our estimations in the life of the red cell

The earlier conceptions of bile pigment as derived exclusively from the breakdown of hemoglobin and as being excreted in its entirety, give the red cell a short life, when calculated on the basis of the known quantitative relationship between hemoglobin and bile pigment Wilber's hypothesis of a conservation of the pyrrole complex for the formation of fresh hemoglobin by reabsorption from the intestine would still further reduce the figure for life span of the red cell It was not until Whipple and Hooper introduced the conception that bile pigment might be derived from other sources than hemoglobin that evidence of a longer life of the red cell became tenable

Following the earlier work, in which calculations were based upon a direct relationship between bile pigment excreted and hemoglobin destroyed, Eppinger in 1913²⁸ Wilber and Addis²⁹ in 1914 and Addis² in 1915 emphasized the probability that bile pigment was reabsorbed from the intestine and used for the formation of hemoglobin as the needs of the organism demanded This theory led to a great deal of experimental work, some of which appeared to support it and some to disprove it

In 1917 Hooper and Whipple³⁰ published the results of some work on dogs which, they considered, indicated that bile pigment was not absorbed from the intestine They studied dogs with biliary fistulas to determine the normal rate of bile pigment excretion, after which they injected from 100 to 300 cc of fresh bile by stomach tube They determined the rate of excretion of bile pigment for six hours and in some cases for fifteen hours afterwards They found no significant increase

In 1923 Broun, McMaster and Rous³¹ repeated this work with an improved technic for collecting the bile which enabled them continuously to obtain the whole twenty-four hour specimen. They worked with dogs and part of their experiments consisted in the injection of sheep bile which contained cholehematin, a substance not found in dog bile. They found this in the dog's biliary secretion and considered this partial evidence that the sheep bile had been taken up from the intestine, although they admitted that cholehematin was an extrinsic substance obtained from the green food of the herbivorous animal. They also fed dog-bile, but in this work their results were not consistent. In some instances they considered that their figures indicated an increase in the output from the biliary collection upon feeding bile, in others no increase was shown. They considered that on the whole their results indicated an enterohepatic circulation of bile pigment.

In 1926 Bollman, Sheard and Mann³² brought a fresh technic to the solution of the question. They compared the bilirubin contents of the venous and arterial blood supply of various organs, including the intestine. They used fasting animals, animals on a mixed diet of meat, bread, milk and syrup, animals given a feeding of cream and egg yolk, and animals given fresh dog bile in amounts of from 100 to 200 cc, injected into the duodenum, the jejunum and the ileum. Comparisons were made of the bilirubin contents of the blood from the mesenteric veins and arterial blood at periods of from thirty minutes to three hours after administration of the bile, and at suitable periods in the fed animals. They had previously found that blood samples withdrawn simulatenously from different arteries of the body contain identical amounts of bilirubin. The bilirubin content of blood from venous sources taken at the same time is greater than or identical with that of arterial blood, depending upon the areas drained by the veins. The findings indicated that bilirubin was added to the blood in the spleen, the bone marrow and the liver. With the same technic they were unable to detect any increase in the blood returning from the kidney, skeletal muscles or the intestine. They conclude that since their method was sufficiently sensitive to detect the addition of bilirubin to the blood as it passes through any of the sites of bilirubin formation, no intestinal absorption occurs under the conditions of their experiment.

Probably the latest contribution to this problem as to whether the bile pigment is absorbed and reutilized comes from some work by Shemin and Rittenburg³³ using the isotope N^{15} . The isotope was incorporated into glycine which had in previous work been shown to be the nitrogenous precursor of the protoporphyrin of hemoglobin. When the isotope containing glycine was fed to man the N^{15} content of the hemoglobin rose sharply, stayed on a level and then fell abruptly to base. The flatness of the curve indicates that there was no reutilization of the labeled nitrogen for hemoglobin formation.

Having apparently disposed of the question of bile pigment reutilization, we come to the even more important one in our assay of the life of the red cell, that of whether or not the bile pigment complex has other sources than hemoglobin.

In 1916 Whipple and Hooper³⁴ reported that bile pigment excretion was increased with carbohydrate feeding. By 1922 the studies on the effect of food had been greatly extended by the workers constituting this group. It was shown that

red meat, cooked liver, hemoglobin and butter fat had a positive effect upon the production of hemoglobin or bile pigment. Next came spinach, full diets of common grain foods and milk. Chlorophyll, clams, onions, lard and codliver oil were inert. At this time Whipple³⁵ formulated the conception of a bile pigment complex which would be an intermediary stage in the development of bile pigment from hemoglobin and would be utilized according to the needs of the organism. He considers that bile pigment output is a result of functional activity of the liver and is not solely the result of the passive elimination of defunct hemoglobin. At the same time he characterized pernicious anemia as a disease which showed an abnormal tendency to pigment production rather than to cell destruction. Preceding this, Ashby, due to a failure to find any increase in destruction of transfused red cells in that disease, had suggested that a retardation in the maturation of the red cells in the bone marrow might account for the accumulations of iron because of non-utilization and that the physiologic stimulus of the anemia might account for the extension of the active bone marrow and the increase in bile pigment production.

In 1923, Rous, Brown and McMaster³⁷ published a series of papers on studies of total bile, using their technic of continuous bile pigment collection. One of these papers was devoted to the question of the relation of carbohydrates to the output of bile pigment. They considered that their results did not substantiate those of Hooper and Whipple. They found an increase in bile pigment production upon carbohydrate feeding followed by a compensatory decrease. They explained this result on the basis of a temporary hastening of the evacuation of the bile pigment from the liver due to deposits of glycogen. In a paper on the relation between blood destruction and the output of bile pigment they described work in which dogs had been intubated with the total removal of bile for periods of three months.³⁸ A secondary anemia developed which showed intercurrent fluctuation accompanied by similar fluctuations in the bile pigment output. The relations between these fluctuations were studied. In addition, some of the dogs were subjected to treadmill exercise and to transfusion of citrated blood. The authors find that the output of bile pigment is not fully reflected in the fall in hemoglobin, which they interpret as blood destruction. They attribute this to a process of pigment conservation which varies in proportion to the body need. They add that "the destruction finds expression in terms of bile pigment and practically at once, and the data support the conception that bilirubin has no other source besides the hemoglobin of destroyed blood."

In the evaluation of all such data as the above we have certain inherent difficulties. Bile pigment can be measured, but blood destruction cannot. The blood count is the resultant of two unknowns—the rate of blood production and the rate of blood destruction. With a decrease in blood production the total red cell count would go down without any change in the rate of blood destruction. If we interpret these increases in bile pigment production which Rous and his co-workers have found associated with the falls in circulating hemoglobin as part of a stimulus to production of the pyrrole complex in answer to the need, they become equally potent arguments for the extra-hemoglobin source of bile pigment.

It would appear that Hawkins and Whipple³⁹ have finally settled the question

by pinning one of the unknown factors, blood production. They did this by removing within a short space of time enormous amounts of blood from dogs. Upon regeneration of the red cells they had a population of corpuscles that were of practically the same age. They varied the procedure by destroying the blood with acetyl phenylhydrazine to avoid removal of material that might be useful in rebuilding corpuscles. The bile pigment output changed from 125 mg per day to 58 mg and remained at this low level because the population of the blood stream was preponderantly young cells that were not being destroyed. After approximately four months the bile pigment rose to a high level. This was interpreted as being the result of the eventual death of the cells that had been formed after the massive hemorrhages. The life span was estimated at 133 days.

THE USE OF DIFFERENTIAL AGGLUTINATION

After the establishment of the human blood groups by Landsteiner, followed by Jansky and Moss, much clinical experience was accumulated with reference to the blood transfusion. By 1918 the question was in debate by the medical profession as to whether or not transfused blood existed in the circulation for even the twenty-two days suggested by the work summarized by Hunter, or, whether it was removed within a few days and any favorable clinical results were due to the supply of raw material from which new cells could be formed more readily.

In 1911 an article by Charles Todd and R. G. White⁴⁰ had appeared in the proceedings of the Royal Society, 'On the fate of the red blood corpuscles when injected into an animal of the same species'. The authors used a highly polyvalent isohemolytic cattle serum produced by injection of cattle with the blood of other individuals. By this technic they had previously reported a high degree of individuality in cattle similar to that found by Ehrlich in goats. This serum was exhausted for the antihemolysins of the corpuscles to be studied. It was used to separate transfused blood from the blood of the recipient. The transfused blood was found to disappear in the course of a few days. The authors found that the injected corpuscles are treated by their host as foreign, and in fact act as antigens, and give rise to the formation of corresponding antibodies in accordance with the ordinary laws of immunity.

In 1918, Ashby⁴¹ at the Mayo Clinic, taking advantage of the difference in agglutinability of the recipient and donor cells in instances of transfusion with the universal donor," published the result of the study of 3 cases in which it was claimed that the transfused blood stayed in the circulation for considerable lengths of time, time enough to produce beneficial results due to functioning cells. Because of the rapid turnover of patients at the Mayo Clinic it was difficult to follow the full span of life of the transfused blood, and nothing was postulated as to this point. Of the 2 cases reported, which remained under observation for forty days, in one, that of a woman who had had a total hysterectomy, the transfused blood had come to base, while in the other, a man who was transfused for simple hemorrhage, there was little sign of disappearance of the transfused blood at the end of this time. Included in this first report were studies checking the quantitative validity of the technic with *in vitro* mixtures of bloods and certain points necessary for

satisfactory results were stressed. There were also included 10 cases studied for only a short time, in which the data indicated a common factor relating the amount of blood transfused, the body weight of the patient and the number of cells found in the blood after transfusion attributable to the transfused blood,²⁵ determined by differential agglutination. Such data were subsequently used in the study of blood volume.

Three papers by the same author followed this initial report.^{42 23 36} They gave data on approximately 40 cases. Many of these patients were suffering from fatal illnesses. Although the longer life of the corpuscle was amply demonstrated in a few patients who were in comparatively normal health, attention was called to the great irregularity in the time taken for elimination of the transfused cells in a group of patients in which it had been possible to follow the count to its extinction. These survival periods ranged from 30 to 110 days. It was argued that transfused bloods, having been taken from normal donors, had equal capacities to survive and that the differences in survival periods were due to an activity of the organism receiving the blood. This argument was offered in conjunction with the data in connection with certain cases in which periodic steplike decreases in the count were seen. The capacity for the long survival of the red cell in the blood stream, however, is seen. In 11 cases that were under observation for periods varying from 22 to 51 days during which no appreciable drop in the count of transfused blood took place, from the case of a man who was in good health who had been transfused for a simple hemorrhage and whose count was followed for 110 days when there was still evidence of some of the transfused blood, from cases of pernicious anemia in which there was evidence of survival of the last of the transfused corpuscles, which were presumably the youngest at the time of transfusion, 95 and 100 days after the transfusion had been given.

In 1922 Wearn, Warren and Ames,²¹ using Ashby's technic, presented prolonged studies on 8 patients from the Medical Service of Peter Bent Brigham Hospital. Four were cases of primary anemia and four of secondary anemia due to nephritis. They report that 'the last of the transfused red blood cells disappeared from the circulation in from 59 to 113 days', 'No difference was noted in a series of observations in the duration of the stay of the transfused red blood corpuscles in the circulation between patients with primary and secondary anemia due to nephritis, and that 'in a single observation red blood corpuscles from a patient with pernicious anemia transfused into another patient with pernicious anemia, behaved as did corpuscles from normal donors'.

By 1926 several criticisms had been leveled against this apparently simple technic of Ashby, notably by Wildegans⁴³ and Gorl.⁴⁴ The criticisms were due to an inability to get quantitative separation of in vitro mixtures of agglutinable and nonagglutinable blood as had been reported by Ashby in the original description of the technic. These failures to repeat the results of Ashby were probably due to the use of serum of insufficient agglutinating strength or to the use of hemolytic serum, both of which were warned against in Ashby's original description of the technic. A possible cause, also, would be insufficient agitation during the initial period of agglutination. The technic was not acquired by these workers.

The most serious criticism of the findings of Ashby and of Wearn, Warren and Ames, indicating a prolonged life for the red cell in the blood stream, came from Isaacs, in 1924.⁴⁵ He reported "The use of agglutination in recognizing the cells of a donor in a mixture of two bloods in a transfused patient is of little value after the number of young cells reaches the number of unagglutinable cells, usually in from two to four days." This statement was based on work using a radical modification in technic, with no report of *in vitro* work to see whether or not the technic gave quantitative separation of an agglutinable from a nonagglutinable blood. The greater part of the work was done upon the blood of dogs in which animal there are not known to be strong isoagglutinins and for which the author gave no evidence that they exist. Work upon 2 human cases was reported, the results of which were entirely at variance with the results already reported with the Ashby technic on some 50 cases by Ashby and by Wearn, Warren and Ames.

Ashby immediately criticized this paper of Isaacs,⁴⁶ in the first place because the immature cells which Isaacs had claimed composed the unagglutinated cells were not found among the nonagglutinated cells by the Ashby technic. The same finding was reported in 1940 by Maizels and Paterson who say "If the unagglutinable cells are immature cells they should show a high retic count, higher than that of the whole blood, but the reverse is the case." In the second place the prolonged rise in the count of unagglutinable cells after a Group O transfusion and the lack of a rise after a like group transfusion reported by both Ashby and by Wearn, Warren and Ames was not explained by Isaacs. It was also pointed out that on the basis of the amount of blood given and the body weight of the two patients, the counts of the unagglutinable blood found by Isaacs subsequent to transfusion would indicate an impossible blood volume relationship, being in one case 25 per cent of the patient's body weight and in the other 75 per cent of the body weight. It was concluded that Isaacs had not accounted for the transfused blood by his technic.

Isaacs' results, however, were considered seriously by the group interested in the longevity of the blood cell and Isaacs, himself, reiterated them in a paper in *Physiologic Reviews* in 1937,⁴⁸ so that at the beginning of World War II when several English groups were studying the effect of storage upon survival of transfused blood for use at the front, Maizels and Paterson⁴⁷ undertook to check on the validity of Isaacs' claims. With reference to Isaacs' criticisms of the Ashby technic they state "It may be said at once that these criticisms are theoretical and unsupported by numerical data, however, since the cell agglutination technique is the only one which permits of a direct measure of cell survival the objections must be considered in detail. The arguments were approximately those used above except that in addition the M and N factors were used to separately agglutinate the donor and recipient cells."

By 1928, however, Landsteiner, Levine and Janes⁴⁹ had offered irrefutable disproof of Isaacs' contention for the short life of the cells by making use of their anti-M and N sera and agglutinating the transfused cells instead of the recipient's cells. They found clumps in the recipient's blood treated with their antiserum for seven weeks after transfusion, when they ceased to examine it. Later Wiener,⁵⁰ using

M antiserum with an M donor, reported that the life of the transfused cell probably averages between 80 and 120 days

The very considerable amount of work which was done at the beginning of the war, checking the various methods for preserving blood and the time allowable for storage, made use of the cell-agglutination technic. This work was carried out by the English Groups,^{47 51 52} by Wiener and Schafer⁵³ in this country and by the Russians in checking their cadaver blood. This work all indicated the long survival of the transfused corpuscle.

DETERMINATION OF THE LIFE SPAN OF THE RED CELL BY USE OF THE ISOTOPE

The problems involved in tagging the red cell by use of the isotope and determining its longevity are: First, to introduce the isotope into the corpuscle in such a chemical combination that it remains in the corpuscle during its life, second, to choose an isotope of some element that will not be reutilized after the corpuscle has disintegrated, and last to choose an isotope that can be studied for a sufficient length of time.

The interesting phenomenon which the use of isotopes has emphasized is that although morphologically the cell and its constituents are intact, the reversibility, within the status of their equilibrium of certain cellular reactions, results in continuous degradation and resynthesis. An isotope introduced into a constituent of the cell which bore such a relationship to the metabolism of the cell would not indicate by its presence the life of the cell, but would merely be an index of the time relationship of the reaction in which the compound was involved.

On the other hand, if the isotope is some element which will be reutilized in the formation of new cells its presence will extend beyond the lifetime of the cells into which it was first introduced. It has long been considered probable that iron split off from hemoglobin upon the formation of protoporphyrin, is quite labile and is readily reutilized. In 1941, Cruz, Hahn and Bale,⁵⁴ working with radioactive iron, reduced the iron reserves of dogs by repeated hemorrhage and fed radioactive iron. This appeared in the blood with the rise of hemoglobin and stayed on a level for seventy-five days when the dogs were treated with acetylphenylhydrazine. The resultant drop in hemoglobin was paralleled by a drop in the radioactivity of the blood which rose to its original height with the regeneration of hemoglobin. The isotope level had not decreased 180 days later. The authors conclude that iron liberated from red cells is utilized readily and nearly quantitatively for the regeneration of hemoglobin in new red cells.

In 1946 Shemin and Rittenberg introduced the isotope N^{15} into several compounds which were of interest in their possible relationship to the synthesis of protoporphyrin of hemoglobin.⁵⁵ Glycine, proline and glutamic acid were chosen because there was a probability that they would be used in the formation of protoporphyrin, leucine was chosen as a representative α -amino acid whose intact carbon chain was unlikely to be used for pyrrole synthesis, and ammonia was chosen to test the nonspecific utilization of nitrogen liberated by deamination of amino acids. These substances were fed to rats whose hemin was subsequently tested for the isotope. It was shown that glycine is a nitrogenous precursor of the

protoporphyrin of the hemoglobin of rats. The authors were of the opinion that the much smaller amount of N^{15} found in the hemin upon feeding of isotope proline, leucine, glutamic acid and ammonia is due to N^{15} enrichment, by the nitrogen of these compounds, of the body nitrogen from which the precursors of heme is synthesized rather than a direct utilization of these compounds.

Having established this fundamental point these workers proceeded to feed N^{15} containing glycine to a man and to study the shape of the curve indicating the appearance in the circulation of this isotope and its disappearance from the circulation. 'The values rose rapidly to a high level, remained practically constant for many weeks and then fell quite sharply to a very low level. This finding indicates that the heme is neither involved in the dynamic metabolic state nor reutilized for hemoglobin formation. On these grounds, the curve of N^{15} concentration of the heme versus time can form a basis for the average life span of the human red blood cell. This was found to be about 127 days.'³³

CONCLUSION

We come then, after following the evidence derived from three separate approaches, to the conclusion that the life span of the red cell approximates the dimension of 110 to 130 days under favorable conditions.

This does not mean, however, that for practical purposes a transfusion lasts for that length of time. The blood transfused consists of cells of all ages up to the full span of four months, and half of them are already half of this age when they are transfused. Neither does it mean that the span of life of the red cell is of this dimension under all circumstances. Hawkins and Whipple reported the figure of 133 days from work on normal dogs. The study of Shemin and Rittenberg using the isotope N^{15} in which they found the life span to be 127 days was made on a normal man. The subjects of transfusion, however, are usually far from normal, therefore the data derived from the cell-agglutination technic has to be considered in relation to the condition of the patient transfused. Ashby (1921), Wearn, Warren and Ames (1922), Wiener (1934), Mollison and Young (1940), and Callender, Powell and Witts (1945),⁵⁶ are agreed upon 120 days as an approach to an optimum length of life for the transfused red cell as indicated by the method of differential agglutination. Ashby (1921), and Wearn, Warren and Ames (1922), are agreed that in pernicious anemia the tenure of life of the red cell is of a similar dimension. But there are other conditions in which the life span of the transfused blood and probably, also, of the patient's own blood, is of much shorter duration.

I have on this occasion reviewed my own studies of transfused Group O blood into recipients with blood of an agglutinable type, of which I have over 80 cases, with few, unfortunately, studied to the extinction of the transfusion. I have endeavored to draw some conclusions from these data by extending the slope of the curve of elimination to a base line. This is admittedly not accurate in the individual case, but appears to give interesting average results. In 8 cases, uncomplicated by malignancy, in which postoperative transfusions were given, the average time taken for unagglutinable cells to come to base was 124 days. In 16 cases of pernicious anemia it was 110 days. In addition there were in these groups cases which

showed no drop in the count while under observation and therefore no estimation could be made. On the other hand 10 cases with malignancy averaged 52 days. Seven cases of jaundice averaged 46 days. In a case of aplastic anemia with smallpox studied for 26 days the curve of the count of transfused corpuscles would have come to base in 41 days, while a case of splenic anemia in an infant by this method showed elimination of a first transfusion in 44 days and of a second in 55 days. In a total of 24 cases, in which hyperthyroidism and severe chronic infection are included, the average of the apparent length of life of the transfused blood was 52 days. But in 5 instances in which death was imminent the life of the transfused cell was even shorter.

It would seem, then, that we will have to regard the erythrocyte not as an entity, but as an integral part of the organism. Castle and Minot⁵⁷ in their article on the anemias in Oxford Medicine introduce Boycott's conception of the "erythron," which is understood to be the circulating blood and the organ from which it arises. I believe, however, that before the picture is complete we will have to consider a broader angle and include the effect of the endocrine system. As we pointed out in the beginning of this review, the red cell, both the compatible transfused cell and that produced in the body, probably is capable of undergoing repair, and it is by virtue of its capacity to repair itself that it survives the buffeting of the circulation. In a body in which the anabolic processes as compared with the catabolic processes are on the down grade, as in the terminal stages of disease, or in the presence of malignancy, one would expect the red cell to suffer with other body tissues and its life in the blood stream to be shortened.

The new knowledge on the interplay between the cortical and anterior pituitary hormones and their control of the up-build and destruction of protein, and their relation to insulin in carbohydrate metabolism as illustrated by the work of the Cori's on the enzyme complex hexosekinase, may be intimately related to the problem of the life of the red cell. This question has already begun to interest biochemists. In the 1946 meeting of the Federation of American Societies for Experimental Biology a study was reported by Gonzales and Angerer⁵⁸ on the effect of adrenalectomy on the respiration of the erythrocytes of rats. They found a 41 per cent decrease in oxygen consumption in a Krebs-Ringer suspension of washed rat red cells five days after adrenalectomy and noted that the decrease was perceptible within forty-eight hours.

If we may assume that the life of the red cell in the rat is longer than five days, which would seem to be a safe assumption, this finding would indicate that the erythrocyte is dependent upon the adrenal for something that maintains its capacity to utilize oxygen and brings it into relationship with the organism in its ability to maintain itself in the circulation.

STUDIES ON FREE ERYTHROCYTE PROTOPORPHYRIN, PLASMA IRON AND PLASMA COPPER IN NORMAL AND ANEMIC SUBJECTS*

By G E CARTWRIGHT, M D , C M HUGULEY, JR , M D , HELEN ASHENBRUCKER, B A , JANE FAY, M D , AND M M WINTROBE, M D , Ph D

THE VARIOUS anemias have been studied and classified clinically, morphologically, therapeutically and to a less extent etiologically, but comparatively few chemical studies have been made. Investigation of the chemical changes accompanying the various types of anemia offers a new approach to their study and gives rise to the hope that as the specific defects are elucidated their correction will become simplified. The purpose of this paper is to present data on free erythrocyte protoporphyrin, plasma iron, and plasma copper in normal subjects and in subjects with various types of anemia.

REVIEW OF LITERATURE

The presence of protoporphyrin free in erythrocytes in addition to that in the hemoglobin molecule was reported by van den Bergh and co-workers¹ in 1928 and since then has been confirmed repeatedly.²⁻⁷ Grotepass⁸ and subsequently Watson, Grinstein and Hawkinson⁶ demonstrated that this protoporphyrin is identical with the protoporphyrin of hemoglobin, namely, protoporphyrin 9, type III. A logical assumption is that this protoporphyrin is an intermediate compound in the synthesis of hemoglobin and that the free material is found because it has not been utilized for hemoglobin synthesis.

The amount of free protoporphyrin in the erythrocyte may be postulated as depending upon the relative rates of (1) synthesis of protoporphyrin from precursors, (2) utilization of the formed protoporphyrin for hemoglobin synthesis, (3) formation of protoporphyrin from hemoglobin in the intact erythrocyte, if such occurs, and (4) destruction of protoporphyrin, if this takes place. This may be represented diagrammatically.

Data have been presented elsewhere¹⁰ which indicate that reticulocytes contain more free erythrocyte protoporphyrin than do mature red corpuscles. It has been reported that the protoporphyrin content of the bone marrow is increased when the percentage of normoblasts is increased.¹¹ In experimental hemolytic anemias the erythrocyte protoporphyrin did not increase when blood destruction was maximal but rose, instead, during the regenerative phase when reticulocytosis was marked.¹⁰ It has been suggested that increased EP usually signifies uncompleted hemoglobin synthesis which may be the consequence

From the Department of Medicine, School of Medicine, University of Utah, Salt Lake City, Utah

* Aided by a grant from the United States Public Health Service, and by grants from the American Cancer Society on recommendation of the Committee on Growth, National Research Council, from the Upjohn Company and from Parke, Davis and Company

of the liberation of immature cells or is due to iron deficiency or to factors interfering with the utilization of iron in the synthesis of hemoglobin is, for example, lead poisoning.^{5, 10}

The manner in which protoporphyrin is broken down is unknown. It has not been demonstrated that destruction can take place in the intact red cell without the porphyrin being first formed into hemoglobin. The intravenous injection of protoporphyrin is not followed by a significant increase in the excretion of either bilirubin or coproporphyrin in the dog.¹² There is evidence, however, to indicate that under certain circumstances increased free erythrocyte protoporphyrin may result from degradation of hemoglobin in intact erythrocytes. It has been demonstrated that following sterile incubation of red cells for twenty-four to forty-eight hours there is an increase in the erythrocyte protoporphyrin.⁵ Furthermore, red cells taken from the splenic vein following splenic stasis were found to have a greater protoporphyrin content than the cells in the splenic artery.¹⁰ Although the demonstration that protoporphyrin is formed from hemoglobin in intact erythrocytes *in vitro* does not necessarily indicate that such a mechanism exists *in vivo*, there is considerable evidence that hemoglobin degradation can take place within the red cell *in vivo*. It would seem, however, that this takes place through a bile-pigment-iron native globin complex similar to or identical with the pseudohemoglobin of Barkan or the verdohemoglobin of Lemberg⁶ rather than by liberating protoporphyrin.

The literature dealing with plasma iron and with iron metabolism in general was reviewed recently by one of us (GEC).¹⁵ Plasma iron has been the subject of many investigations. Early work was unsatisfactory because of lack of reliable methods. Several satisfactory methods are now available.^{15, 11, 1} It seems clear that plasma iron functions as transport iron. The amount of iron in the plasma is affected by the rate of absorption of iron, the balance between that going to and from the tissues, and the equilibrium between the amount used for hemoglobin formation and that coming from hemoglobin catabolism. Recent studies have shown that the iron in plasma is bound by a specific β_1 globulin (Fraction IV-7 of Cohn).^{16, 17}

The copper content of plasma in anemic states has been studied very little. Until recently, progress in this field of investigation was retarded by the lack of a simple reliable method. The normal serum copper content has been reported by several investigators to be approximately 70 to 160 μg per cent.¹⁸⁻²¹ Elevated serum copper values have been reported in pregnancy,^{19, 20} and in infections accompanied by anemia.^{19, 21, 22} Plasma copper values in other clinical states accompanied by anemia have not been reported except by Locke, Main and Rosbach²³ and it has been shown that the method which they use is unreliable.¹⁸

Keilin and Mann²⁴ isolated a copper-protein compound of unknown function from serum as well as from red cells to which they gave the name of haemocuprein. The significance of this compound is unknown.

METHODS

The hematologic methods used in this study have been described elsewhere.² Hemoglobin was determined by the photoelectric oxyhemoglobin method, using an Evelyn photoelectric colorimeter standardized by the Van Slyke procedure. Erythrocyte protoporphyrin determinations were made by the method of Grinstein and Watson.²⁶ The plasma iron was measured according to the procedure of Kitzes, Elvehjem and Schutte¹³ or by the method of Barkan and Walker.¹⁴ Both methods gave excellent recoveries (95 to 103 per cent of added iron). The method of Cartwright, Jones and Wintrobe¹⁸ was followed for the determination of plasma copper. This method has been shown to be accurate within ± 10 per cent.

Values for erythrocyte protoporphyrin (EP) are expressed throughout the paper in μg per 100 ml of red blood cells. Plasma iron (PI) and copper (PCu) are expressed in μg per 100 ml of plasma. Ht refers to volume of packed red cells in ml/100 ml. MCV refers to mean corpuscular volume in μm . MCH refers to mean corpuscular hemoglobin in μg . MCHC refers to mean corpuscular hemoglobin concentration in per cent.

Each of the three chemical determinations, EP, PI and PCu, were done several or sometimes many times on each patient. The values expressed in the tables are either representative or are means for the given case.

RESULTS

A Normal values The values for free erythrocyte protoporphyrin (EP), plasma iron (PI) and plasma copper (PCu) determined in normal adults are presented in tables 1 and 2. The subjects studied were not usually examined completely but they were apparently healthy. Although the ages of the 68 men and 66 women varied from 20 to 63 years, there was a disproportionate number of young individuals,

approximately two-thirds of each group being between 20 and 30 years of age. However, the data do not suggest that there is any variation related to age. In many of the individuals examined, several determinations were made of one or more of the three chemical constituents studied. The figures analyzed in tables 1 and 2 represent a single value for each person, usually the first obtained in the year 1947.

A total of fifty-six EP determinations in 33 males and fifty-two determinations in 33 females has been made. A frequency distribution curve of the determined values of erythrocyte protoporphyrin reveals a marked skew to the right (fig. 1). By using the logarithm of each value a curve more nearly approaching the normal was obtained. The analysis in table 1 was therefore carried out by this method. In males the observed values ranged from 13 to 70 $\mu\text{g per 100 ml}$ of red blood cells.

but only three values were above $57 \mu\text{g}$. In females the range was 16 to $140 \mu\text{g}$ but only one value was below $20 \mu\text{g}$ and only two were above $68 \mu\text{g}$. The difference between the geometric means for the two sexes is suggestive but not highly significant since the difference is only 1.7 times the standard error of the difference. Slight skew is still present after attempted normalization by use of logarithms and it is our conclusion that the standard deviation given in table 1 is too large. From inspection of the frequency distribution curve we have arbitrarily selected 13 to $55 \mu\text{g}$ per 100 ml of RBC as the normal range in males and 16 to $70 \mu\text{g}$ as the normal range in females. No attempt has been made to determine in detail the variation

FIG. 1. Distribution of normal values for erythrocyte protoporphyrin. The graphs at the right are plotted in logarithmic values. The vertical lines represent the mean, ± 2 S.D., and -2 S.D.

in EP occurring over a period of time in individuals. The variation was usually not marked. The variation in females was not related to the menstrual cycle. Simultaneous reticulocyte counts were not done.

A total of ninety-four determinations of plasma iron on 49 normal males and one hundred and two determinations on 43 normal females has been made. The frequency distribution approximates a normal curve in each sex. The means for the two sexes are almost identical and the standard deviations are of the same order. As can be seen from table 2, the variation in normal values is great. This seems to be a reflection of the variation in each individual. In each of 3 males and 6 females from six to twenty-one determinations were made over a period of six months to two years. The means for these 9 individuals ranged from 68 to $140 \mu\text{g}$ per cent

However, the variation in each individual was of the same order as that between the individuals. Thus, the average coefficient of variation in these 9 individuals was 40 per cent while that of the entire group was 31 per cent. Because of the close approximation of the distribution of plasma iron values to the normal curve the mean value ± 2 standard deviations has been used to indicate the normal. No relationship was noted between the plasma iron levels in females and the menstrual cycle. In one individual a series of determinations was made during the course of the day. In this instance there was no definite trend, the values from one morning to the next varying more than throughout the day. No postprandial change was noted in this individual.

A total of seventy-five determinations of plasma copper on 52 normal males and seventy-five determinations on 53 females has been made. The frequency distribution curve in males approximates a normal curve but in females, though the range is the same as in males, most of the values are grouped close to the mean. The mean for the females is significantly higher than that for males. The variation was not great, the coefficient of variation being 13.6 per cent for males, 8.6 per cent for females, and 9.5 per cent for the group as a whole. The coefficient of variation in 4 males and 5 females in each of whom five determinations were made was 5.4 to 16.1 per cent with an average of 10.9 per cent. The mean value ± 2 standard deviations has been used to indicate the limits of normal.

B Pernicious Anemia The results obtained in 20 patients with pernicious anemia in relapse are shown in table 3. Erythrocyte protoporphyrin determinations were

made on 17 patients. In 16 of these the values were within the normal range and in one patient (S S) the values were low repeatedly. The mean for the entire group was $31 \mu\text{g}$ per 100 ml of red blood cells as compared with the normal of $35 \mu\text{g}$ (table 1). One patient (R T) is of particular interest. This patient was admitted to the hospital on November 15, 1945, in relapse at which time the EP was $36 \mu\text{g}$. She responded well to folic acid therapy but failed to return and received no further therapy. She was readmitted in relapse one year later with fever and sub

FIG 2 Pernicious anemia in relapse (case D M) treated with folic acid orally. During therapy hypoferrremia developed and there was a gradual rise in EP to above normal. There was no significant change in plasma copper.

PCu refers to plasma copper expressed in μg per cent, PI to plasma iron expressed in μg per cent, EP, free erythrocyte protoporphyrin expressed in μg per 100 ml of red cells, Ht, volume of packed red cells in ml per 100 ml, RBC, red cell count in millions per c mm. The reticulocytes are expressed as per cent of red cells.

acute bacterial endocarditis. On the second admission the volume of packed red cells was 19 ml per 100 ml, the mean corpuscular volume 110μ and the EP $290 \mu\text{g}$ although the plasma iron was $268 \mu\text{g}$ per cent. Thus, it seems, patients with pernicious anemia in relapse are, at least in the presence of infection, capable of synthesizing excess protoporphyrin. In those patients who showed a satisfactory response to liver extract or folic acid therapy, there was a marked rise in EP above normal during the reticulocytosis. As the reticulocytosis subsided there was a fall in EP. This is not demonstrated in figures 2, 3 and 4 since the patients were given suboptimal doses of folic acid and a marked reticulocytosis did not occur. A sharp

rise in EP associated with reticulocytosis has been observed in other patients treated with optimal doses of liver or folic acid ¹⁰ As demonstrated in figures 2, 3, and 4, as the anemia was relieved, there was a gradual rise in EP to the upper limits of normal. In table 4, values for EP are presented for patients in relapse and remission. In remission the EP tended to be in the upper limits of normal or even above normal. It is of interest that EP in remission was always higher than during relapse.

Plasma iron determinations have been made on 28 patients with pernicious anemia in relapse. The data on 20 of these patients are presented in table 3. Of the

FIG 3 Pernicious anemia in relapse (case M. B.) treated with folic acid orally, 5 mg per day. During therapy slight hypoferrremia developed and there was a rise in erythrocyte protoporphyrin. There was no significant change in the plasma copper. For symbols see figure 2.

28 patients, in 16 (57 per cent) the values were within the normal range, in 11 (39 per cent) there was an elevation of the plasma iron, and in one patient the value was below the normal. Whatever the initial plasma iron may have been, hypoferrremia developed during the stage of rapid blood regeneration following therapy. This is illustrated in figures 2 and 3. In many the hypoferrremia persisted into the remission (table 4).

Plasma copper determinations have been made in 12 patients with pernicious anemia in relapse (table 3). The mean for the entire group was 137 μ g per cent. In 9 patients the values were within the normal limits and in 3 hypercupremia was noted. During therapy and in remission (table 3) there was no consistent trend in

either direction although in the one patient with an initial low-normal value there was a significant rise from 86 μg to 125 μg

C Iron Deficiency The results obtained in 13 patients with varying degrees of anemia due to iron deficiency are presented in table 5. Erythrocyte protoporphyrin determinations were made on all 13 and in each case the value was found to be above the normal. The mean for the group was 207 μg per 100 ml of red blood cells. No correlation between the degree of microcytosis or the degree of hypochromia and the magnitude of EP increase was noted. There was a rough correlation between the duration of the anemia and the level of EP. During the first

FIG. 4. Pernicious anemia in relapse (case T T) treated with folic acid orally, 5 mg per day. During therapy a slight hypoferrremia developed and there was a gradual increase in protoporphyrin. There were rather large fluctuations in plasma copper. For symbols see figure 2.

10 to 20 days following the onset of iron therapy, that is, during the period of reticulocytosis, there was a slight increase or no change at all in the EP. Then as the volume of packed red cells, mean corpuscular volume and mean corpuscular hemoglobin concentration returned to normal the EP diminished. This reached normal only some time after the blood had returned to normal (figs 5, 6, 7).

Plasma iron determinations were made in 13 patients. The results are presented in table 5 and are uniformly low. The mean for the entire group is 23 μg per cent as compared with the normal of 105 μg . During therapy (figs 5, 6, 7) there was a slow rise in plasma iron but not until some time after the blood had returned to normal did the plasma iron reach normal.

Plasma copper determinations were made in 8 patients (table 5). In 6 the values were found to be high and in 2 the values were within normal limits. No cor-

relation could be found between the degree of anemia and the degree of hypercupremia. Plasma copper was followed during therapy in one patient (fig 7). In this patient there was a fall in the copper which began about twenty days after the onset of therapy and reached normal at about the time the blood returned to normal and before the plasma iron or EP had reached normal.

FIG 5 Iron deficiency anemia (case G M) with hypoferrremia and an increase in EP. Treatment with ferrous sulfate was followed by a significant, though delayed, fall in EP and a gradual increase in plasma iron as the anemia was relieved. VPRBC refers to volume of packed red cells in ml per 100 ml (Ht), MCV, to mean corpuscular volume in μ , MCHC, mean corpuscular hemoglobin concentration in per cent. For other symbols see figure 2.

D Anemia of Infection As previously reported, the anemia associated with chronic infection is accompanied by an elevated erythrocyte protoporphyrin, low plasma iron and high plasma copper.²² The results in 10 patients not previously recorded are presented in table 6. These data confirm our previous findings. The erythrocyte protoporphyrin was elevated in 9 of the 10 patients, hypoferrremia and hypercupremia were present in all those so examined. A number of additional patients with acute and subacute infections have been studied and data are now available concerning the rapidity and sequence of the changes in relation to the onset of the disease and during convalescence.

FIG 6 Iron deficiency anemia (case E M) with hypoferrremia and an increase in EP. During therapy with ferrous sulfate there was a significant decrease in EP and a gradual rise in plasma iron. The volume of packed red cells and indices reached normal before the EP returned completely to normal. For symbols see figures 2 and 5.

FIG 7 Iron deficiency anemia (case D L) with hypoferrremia, hypercupremia and increase in EP. During therapy with ferrous sulfate a marked drop in plasma copper took place. There was an initial increase in EP followed by a drop to normal. The plasma iron rose gradually. For symbols see figure 2.

In acute infections with fever such as uncomplicated lobar pneumonia, bacterial meningitis, pharyngitis, scarlet fever and otitis media, hypoferremia was found to develop within a few days after the onset of fever. This is illustrated in 2 patients with meningococcal meningitis (fig 8). When the disease was of short duration the plasma iron rose when the fever subsided and no anemia developed. Hypoferremia appears to be the first change to take place and occurs in a variety of conditions associated with fever. In figure 9 the effect of induced fever (typhoid vaccine) on the plasma iron is demonstrated. With each paroxysm the iron dropped markedly and returned rapidly to normal shortly after the cessation of fever. No anemia developed and there was no significant change in plasma copper or rise in erythrocyte protoporphyrin.

The effect on the plasma iron of a more prolonged illness is demonstrated in figures 10 and 11. In patient W V (fig 10) there was an initial hemolytic phase with slight jaundice accompanying lobar pneumonia. The total serum bilirubin was 1.5 mg per cent. With this there was an initial hyperferremia which was followed by the hypoferremia usually associated with infection. This persisted for about twenty-five days without anemia developing. Patient I C (fig 11), a woman 36 years of age who had pneumonia and an acute lung abscess, was seen on about the twenty-first day of illness. The plasma iron at this time was 30 μg per cent and the volume of packed red cells 35 ml. The disease responded rapidly to parenteral penicillin therapy and the plasma iron rose promptly. Two patients (F L, pyo-nephrosis and D S, empyema) with more chronic illnesses are described in figures 12 and 13. Significant anemia was present in both. The plasma iron did not reach normal in either patient until after the anemia disappeared.

In acute infections with hypoferremia no change in EP has been noted. This is illustrated in figures 8, 9 and 11. Only when the infection persisted for a month or more or when significant anemia developed did a rise in EP occur. This rise sometimes reached its maximum after the maximal development of anemia. This is illustrated in figure 14. Return of EP to normal took place slowly (figs 10, 12, 13 and 14) and did not reach normal until long after the anemia had disappeared.

FIG 8 The effect of acute infections on the plasma iron as exemplified in two patients with meningococcal meningitis (J V and N H). Hypoferremia developed early in both patients. The iron returned rapidly to normal as the fever subsided. No anemia developed and there was no increase in EP. For symbols see figure 2.

The rise in EP seemed to be correlated with the duration of the infection and to a less extent with the severity of the anemia.

The rise in plasma copper took place some time after the development of hypoferremia but was observed before or in the absence of a rise in EP (fig 11). As can be seen in figure 9 no significant change took place in the plasma copper during the paroxysms of fever. In chronic infections with anemia (table 6) hypercupremia was almost invariably present. The copper returned to normal more rapidly than did the EP or iron and became normal about the time of the disappearance of anemia, as illustrated in figure 10.

FIG 9 The effect of induced fever (typhoid vaccine) on the plasma iron With each paroxysm the plasma iron dropped markedly and returned to normal shortly after the cessation of fever There was no significant change in the plasma copper For symbols see figure 2

FIG 10 Unresolved lobar pneumonia (case W V) There was an initial hemolytic phase with jaundice, bilirubinemia and hyperferremia Following this hypoferremia developed and a rise in EP occurred For symbols see figure 2

FIG 11 A patient with lobar pneumonia and early lung abscess (case I C) with anemia, hypoferrremia and hypercupremia which responded well to parenteral penicillin. As the anemia disappeared the plasma iron rose and plasma copper returned to normal. There was no significant change in EP. For symbols see figure 2.

FIG 12 Chronic infection (pyonephrosis, case F L) with anemia, hypoferrremia and an increase in EP. Kidney function was not diminished. Following nephrectomy the anemia disappeared, the plasma iron rose, and the EP decreased. For symbols see figure 2.

FIG 13 Chronic infection (empyema, case D S) with anemia, hypoferremia and an increase in EP. As the infection subsided the EP diminished to normal and the plasma iron rose. For symbols see figure 2.

FIG 14 Chronic infection (lung abscess, case A R) with anemia, hypoferremia, hypercupremia and an increase in EP. The hypoferremia and hypercupremia developed early. The maximal rise in EP occurred later at the time when the anemia was most severe. This patient was unusual in that the plasma iron rose in spite of persistent anemia. For symbols see figure 2.

It is interesting that one patient with anemia and chronic osteomyelitis developed severe nephritis during the course of his illness. The serum albumin fell to 1.73 grams per cent and the serum globulin to 1.79 grams per cent. At the same time the plasma copper dropped from 246 μg per cent to 40 μg per cent and remained at this low level.

E Anemia of Nephritis The results in 10 patients with anemia associated with various types of nephritis are presented in table 7. In 8 of the 10 patients the erythrocyte protoporphyrin was elevated and in 2 the values were normal. In 4 of the patients the plasma iron was low and in 6 normal. Plasma copper determinations were made on 5 patients. In 4 the values were high and in the remaining patient the value was normal. Sufficient study has not been made to correlate

these chemical changes with the type of nephritis nor with the other metabolic changes which take place in this disease.

F Lymph node disorders and Leukemia Observations in 19 patients with various types of lymph node disorders and leukemia are presented in table 8. All determinations were made prior to treatment with x-ray, nitrogen mustard or urethane. Erythrocyte protoporphyrin determinations were made on 19 patients. In 12 patients the values were elevated and in 7 normal. Plasma iron determinations were made on 19 patients. In 12 patients the values were normal, in 6 low, in 1 elevated. Determinations of plasma copper were made in 6 patients and values greater than normal were found in all. The rise in EP was more marked in the 'lymphoma' group than in the leukemia group. Hypoferremia was not observed in the leukemia group.

G Thalassemia Observations in 6 patients with thalassemia minor and 5 patients with thalassemia major are presented in table 9. Unfortunately, EP determinations

CHEMICAL CHANGES IN NORMAL AND ANEMIC SUBJECTS

could not be carried out except in one patient In all 6 of the patients with the minor variant of the disease the serum iron was normal In 4 of the 6, hyper-

† Infection (T 101°)

cupremia was present In thalassemia major hyperferremia was present in 4 of the 5 patients In the fifth an infection with fever was present and the iron was within

the normal limits. In the 3 patients with the major form of the disease, in whom serum copper determinations were made, hypercupremia was present in each.

In figure 15 the negative effects of intravenously administered pyridoxine on the hyperferremia of two patients with thalassemia major are presented. These same 2 patients had been previously reported as benefiting from combined prolan B and pyridoxine therapy.²⁷

H *Miscellaneous conditions* Observations in a variety of hematologic conditions other than those discussed above are presented in table 10. Several findings are

FIG 15 Two patients (N P and A P) with thalassemia major and hyperferremia. The hyperferremia was not affected by intravenous administration of 50 mg pyridoxine hydrochloride daily. For symbols see figure 2.

worthy of comment. In the 4 patients with aplastic anemia who were studied the plasma iron was markedly elevated in each. Erythrocyte protoporphyrin determinations were made in 2. In one patient the value was slightly elevated and in the other normal. Two patients with myelophthisic anemia were found to have high EP. A patient with hemochromatosis had a normal plasma iron and a low plasma copper. In 2 patients with plumbism there was a marked elevation of the EP. Sufficient data are not available on hemolytic anemia to draw conclusions since only 2 patients were studied and the results differed.

DISCUSSION

Our values for the normal EP correspond with those which Watson, Grinstein and Hawkinson⁵ obtained in 12 normal individuals, although the range in our

series is somewhat higher. The data for normal plasma iron are similar to those recorded by others¹⁵ except that, whereas most observers have found that the mean value for females is significantly lower than for males, in our series the means were

almost identical. The normal plasma copper values also agree with those obtained by others using reliable methods.¹⁸⁻²¹

In table 11 the results of erythrocyte protoporphyrin, plasma iron and plasma copper studies in a variety of clinical conditions associated with anemia are summarized. In general, it was found that in pernicious anemia in relapse the EP was

normal, the plasma iron normal or high and the plasma copper usually normal. Anemia due to iron deficiency and chronic infections was accompanied by an elevated EP, hypoferremia and hypercupremia. In nephritis with anemia the EP was generally increased, the plasma iron was low or normal and the plasma copper was increased. Anemia associated with lymph node disorders or leukemia was accompanied by a normal or high EP, a low or normal plasma iron and an increase in plasma copper. In thalassemia minor the serum iron was normal, hypercupremia was found in 4 out of 6 patients. Thalassemia major was accompanied by both hyperferremia and hypercupremia. Hyperferremia was present in all 4 patients with aplastic anemia who were studied. In 2 patients with plumbism there was a marked increase in EP. Hypocupremia was encountered only twice, in one patient with severe nephritis and hypoalbuminemia and in one patient with hemochromatosis.

TABLE II—*Summary of the Data*

In general it was found that in conditions characterized by hypoferremia, the EP and plasma copper were elevated (anemia of infection, iron deficiency, nephritis, lymph node disorders and leukemia). Analyzing the data in another way, it would seem that there was an increase in EP in anemic states associated with a normoblastic bone marrow due to a disturbance in hemoglobin synthesis, i.e., iron deficiency, anemia of infection, nephritis, lead poisoning and some cases of "lymphoma" and leukemia. In contrast, in pernicious anemia, which is characterized by a megaloblastic bone marrow, there was no increase in the protoporphyrin content of the erythrocytes. These observations are in accord with Stasney's direct observations on the protoporphyrin content of various types of bone marrow.¹¹ His studies suggested that normoblasts contain protoporphyrin in considerable amount, while megaloblasts do not.

A high EP has not been found, however, in all conditions associated with a normoblastic bone marrow. Thus, in the bone marrow of patients L. S. (Banti's syndrome), W. G. (Banti's syndrome) and N. A. (congenital hemolytic jaundice),

42, 32 and 40 per cent, respectively, of all of the nucleated cells were normoblasts. Yet the EP values in the blood were 35, 62 and 45 μg respectively. Again, in pyridoxine deficiency anemia in swine¹³⁻²⁹ low values for EP have been found in the face of normoblastic marrow hyperplasia. Watson⁶ determined the EP in a typical case of thalassemia major and found it to be only 20 μg per 100 cc. He speculated that this might be because protoporphyrin is not formed in appreciable amounts in the early erythroblast stage. This could not be the explanation for the essentially normal EP values in our cases, cited above, since the normoblasts in the bone marrow were late forms. Further studies of the EP content of various types and stages of red blood cells are needed.

Theoretically it would seem that if hemoglobin synthesis is retarded due to factors other than a deficiency in protoporphyrin synthesis, the amount of free protoporphyrin might be increased since protoporphyrin would not be the limiting factor. This can be visualized as follows:

- (a) Porphyrin precursors \rightarrow Protoporphyrin
- (b) Protoporphyrin + Fe + Globin \rightarrow Hemoglobin

If reaction (b) does not proceed and reaction (a) continues, there would be an excess formation of protoporphyrin. By the same reasoning if reaction (a) is the limiting factor it might be expected that the EP would be low or normal.

As indicated earlier, there is evidence that reticulocytes contain more free protoporphyrin than mature cells.¹⁰ It is not known whether this represents a small excess left over during hemoglobin synthesis or is merely a degradation product of hemoglobin. It would seem more logical to assume that the presence of free protoporphyrin in reticulocytes represents uncompleted hemoglobin synthesis. In the anemia of infection hemoglobin synthesis has been shown to be impaired.²² An increase in EP under such circumstances could be readily understood. In iron deficiency anemia, lack of iron is the limiting factor. If there is no defect in protoporphyrin synthesis, one would expect an increase in EP. Any other conditions which impair hemoglobin synthesis without interfering with protoporphyrin production should be characterized by increased EP—unless protoporphyrin is broken down or removed at a rate sufficient to prevent accumulation. We have postulated that in pyridoxine deficiency protoporphyrin synthesis may be impaired²⁹ whereas in pernicious anemia, protoporphyrin accumulation may be prevented by its conversion to bilirubin,³⁰ thus explaining the low and normal EP values observed in these conditions, respectively, both of which are characterized by hyperferremia.

In the last analysis, however, one must concur with Watson who pointed out⁶ that until it is determined whether the protoporphyrin of reticulocytes is merely a small excess left over during hemoglobin synthesis or is purely a degradation product of hemoglobin and until it is known whether or not protoporphyrin is eliminated or built up into additional hemoglobin in the circulating erythrocyte, its significance will remain uncertain.

The significance of the plasma iron is clearer than that of free erythrocyte protoporphyrin. Our observations are consistent with those described by

previous investigators, cited already. In conditions in which the amount of iron absorbed is decreased (inadequate dietary intake of iron, etc.) and in conditions in which the rate of elimination is increased (hemorrhage), the plasma iron is low. In conditions in which the amount of iron going to the tissues is increased (anemia of infection), or in conditions in which hemoglobin is being rapidly synthesized (e.g., pernicious anemia during treatment), the plasma iron is low. In conditions in which hemoglobin synthesis is reduced due to factors other than a lack of iron (pernicious anemia in relapse, thalassemia major, aplastic anemia, pyridoxine deficiency in swine), the plasma iron is high. In conditions in which hemoglobin catabolism is accelerated (hemolytic anemia) the plasma iron is high. More than one of these factors may be operating, as in hemolytic anemia where both hemoglobin synthesis and hemoglobin destruction are accelerated. In this event the plasma iron is dependent upon the balance of these factors and generally fluctuates, depending upon which factor predominates at a given time.

Knowledge of the absorption, function and metabolism of copper, especially in relation to erythropoiesis, is so limited that interpretation of our findings is difficult if not impossible. In general, plasma copper is a more stable constituent of blood than is the EP or plasma iron. An elevation of plasma copper has been a rather consistent finding in (1) the anemia of infection, (2) "lymphomas," (3) leukemia, (4) iron deficiency, (5) nephritis, and (6) thalassemia. No change was noted in pernicious anemia. Low plasma copper values were infrequent. We have observed hypocupremia only twice. In the patient with osteomyelitis and hypercupremia who subsequently developed nephritis, hypoalbuminemia and hypocupremia the last finding might be explained on the basis of the hypoalbuminemia if copper is bound to an albumin in the serum. The finding of hypocupremia in the patient with hemochromatosis is interesting in view of Mallory's theory²⁸ that hemochromatosis is due to copper poisoning. The hypocupremia might indicate rapid mobilization of the copper into the tissues.

SUMMARY

1. A total of 108 erythrocyte protoporphyrin determinations has been made in 66 normal individuals. The geometric mean \pm standard error of the mean was 31 (26-38).

2. A total of 196 determinations of plasma iron in 92 normal individuals was made. The mean \pm standard error of the mean was 104.7 ± 3.4 μ g per cent.

3. In a total of 150 determinations of plasma copper in 105 normal individuals, the mean \pm standard error of the mean was 118.6 ± 1.2 μ g per cent.

4. No significant difference in plasma iron was noted between the sexes but in females the plasma copper was significantly higher and the erythrocyte protoporphyrin slightly higher than in males.

5. Erythrocyte protoporphyrin, plasma iron, and plasma copper determinations have been made in over 112 patients with a variety of clinical conditions associated with anemia. In general, it was found that in pernicious anemia in relapse the erythrocyte protoporphyrin values were normal, the plasma iron normal or high and the plasma copper usually normal. Anemia due to iron deficiency as well as the

anemia of infection were accompanied by high values for erythrocyte protoporphyrin, hypoferremia and hypercupremia. In nephritis with anemia the erythrocyte protoporphyrin was generally increased, the plasma iron low or normal and the plasma copper increased. Anemia associated with lymph node disorders or leukemia was accompanied by a normal or high EP, a low or normal plasma iron and an increase in plasma copper. Thalassemia major was found to be accompanied by both hypercupremia and hyperferremia, in thalassemia minor the serum iron values were normal although hypercupremia was found. Hyperferremia was noted in aplastic anemia. In cases of plumbism the erythrocyte protoporphyrin was markedly increased. Hypocupremia was noted only twice, in one patient with severe nephritis and hypoalbuminemia and in one patient with hemochromatosis.

ACKNOWLEDGMENTS

For samples of plasma from patients with thalassemia we are indebted to Drs W N Valentine, Rochester, N Y, P Sturgeon, Los Angeles, and L K Diamond, Boston. The following gave valuable technical assistance: Misses Mary Iles, Betty Tatting and Wanda Worth.

STUDIES IN IRON TRANSPORTATION AND METABOLISM

VI ABSORPTION OF RADIOACTIVE IRON IN PATIENTS WITH FEVER AND WITH ANEMIAS OF VARIED ETIOLOGY*

By REUBENIA DUBACH, PH D, SHEILA T E CALLENDER, M D, AND
CARL V MOORE, M D

RECENT studies of iron utilization have demonstrated that intravenously administered tracer doses of radioactive iron are utilized completely for hemoglobin synthesis by afebrile, iron-deficient patients or animals, and almost completely by normal subjects.¹ On the other hand, when hemoglobin synthesis is impaired, as in patients with refractory anemia or untreated pernicious anemia, in patients with febrile disorders, and in pigs with infection or pyridoxine deficiency, both the rate and completeness of utilization are decreased.¹⁻³ It was discovered, furthermore, that the amount of tagged iron which appears as hemoglobin in the peripheral blood of subjects with hemolytic anemia cannot be used as a measure of iron utilization because of the rapid rate at which isotopic hemoglobin is removed from the circulation. These results clearly indicate that the radioactive iron technic for studying iron absorption, as used in the past,⁴⁻¹² may give erroneously low values because only iron built into hemoglobin is measured, the assumption that this amount equals the quantity absorbed is not always justified. In the face of this new evidence, it is necessary to re-evaluate the ability of patients with impaired hemoglobin formation to absorb iron. Absorption of the metal by normal subjects should also be restudied because even though normal persons use tracer amounts of injected iron completely or almost completely for hemoglobin synthesis, absorbed iron goes into the portal rather than the systemic circulation and may, therefore, be handled in a different way. This report describes experiments designed to meet the above objections and to discover the physiologic pattern of iron absorption under a variety of pathologic influences.

The isotopic method for studying iron absorption has been extended to include not only measurement of the amount of iron converted into hemoglobin after an oral dose, but also determination of the unabsorbed portion which is eliminated in the feces. A standard dose of 1 mg of iron per kilogram of body weight has been selected. Any portion of the test dose not accounted for in the circulating hemoglobin and in the recovery from feces represents iron that has been absorbed but not immediately utilized. With this approach, the principle that iron-deficient subjects absorb larger amounts than do normal persons has been confirmed.^{4, 13, 14} The amount retained by healthy men and women, however, has occasionally exceeded 10 per cent, because of the error inherent in the method, it was not possible to determine accurately how much might be stored without being used immediately for hemoglobin, but the quantity was not large. It was possible to demonstrate that patients with refractory anemia, untreated pernicious anemia,

From the Department of Internal Medicine, Washington University School of Medicine, St Louis, Mo

* This work was supported by a grant from the John and Mary R. Markle Foundation

and fever often did absorb more iron than they were able to build into hemoglobin during the period of observation. One woman with Hodgkin's disease and hypochromic anemia, for instance, retained 50 per cent of the oral dose but used for hemoglobin synthesis only one-third of the amount absorbed.

These results are of considerable theoretic interest. It is now believed that the animal organism has an extremely limited capacity to excrete iron^{14, 15} except by hemorrhage, and that the intestinal mucosa protects the body from accumulating toxic amounts of the metal by accepting or rejecting iron according to need.^{8, 16, 17} The intestinal mucosa, according to this concept, is one of the major regulators of iron metabolism. Evidence indicating that patients with hypochromic anemia absorb more iron than do normal persons is compatible with this theory. However, the observation that patients with untreated pernicious anemia and refractory anemia absorb appreciable amounts of the metal in spite of the relatively large amounts of iron in their tissues, shows the regulatory effect of the intestinal mucosa to be less precise than was formerly believed. •

MATERIAL AND METHODS

The subjects who volunteered for this study were healthy medical students, members of the laboratory staff, and patients on the Medical Service of the Barnes Hospital. The test dose of radioactive iron was given orally, at a level of 1 mg. of iron per kilogram of body weight, as ferrous chloride, reduced from the ferric state with ascorbic acid. The usual procedure was to give the test dose after a night's fast, but in a number of experiments the iron was given 3 to 5 hours after a meal. In one instance, through an error, the test dose was given immediately after the patient had eaten lunch and excellent absorption of the metal occurred (J. L., first dose, table 2, fig. 1). Quantitative fecal collections were made until radioactivity measurements showed that the 24 hour specimen contained less than 0.5 per cent of the activity in the test dose. In most of the subjects, fecal collections could be suspended after the sixth or seventh day. In two instances they were continued until the twelfth day. Since the method depended on getting complete stool collections, extreme vigilance was exercised by the laboratory staff. Only experiments in which there was satisfactory evidence of reliable collections have been included in the study. Blood was drawn at intervals of three days for determination of the radioactive iron in hemoglobin. The total amount of radioactivity in the peripheral blood was calculated by assuming the blood volume to be 80 cc. per kilogram of body weight. The error introduced by this assumption did not influence interpretation of results since the amount of iron found in the blood was usually small as compared with that recovered from the feces. Details of the technics for making the radioactivity determinations have already been published.¹⁸

The fresh fecal specimen was weighed and mixed thoroughly with water to which enough concentrated hydrochloric acid was added to bring the final concentration to approximately 0.6 N (50 cc. concentrated HCl per liter). The suspension was transferred quantitatively through a funnel to a liter volumetric flask, and enough water was added to adjust the volume to exactly one liter. The flask was stoppered and shaken vigorously for about three minutes. As quickly as possible, an aliquot sample (one twentieth to one tenth) of the stool suspension was measured into a Kjeldahl flask. The mixture was then digested with sulfuric and perchloric acids. The cooled digest was transferred to a volumetric flask, and an aliquot portion was taken for measurement of radioactivity. Five milligrams of inert iron were added as a carrier to the aliquot in a 40 cc. centrifuge tube and the iron was precipitated with NaOH, using phenol red as an indicator. The precipitate was thrown down by centrifugation, the supernatant liquid was discarded, and the precipitate was dissolved in 0.3 cc. of 3 M H₂SO₄. To this solution were added in the centrifuge tube about 10 cc. of a mixture of three parts of saturated ammonium oxalate solution and one part of saturated oxalic acid solution. The precipitated calcium and magnesium oxalate salts were thrown down by centrifugation and the supernatant solution was transferred quantitatively to the electroplating cell. The precipitate of oxalates was stirred with a few drops of 3 M H₂SO₄ and

10 cc of the oxalate mixture, the tube was again centrifuged and the washings were combined with the material already in the electroplating cell. From this solution, the iron was electroplated onto a copper disk¹⁸ and its radioactivity was measured with a Kip type Geiger counter tube.

Attention is directed to the fact that iron was not extracted from the fecal specimens by ether, as was done in certain earlier experiments.¹ Ether extraction was unnecessary because the radioactivity in these fecal specimens was great enough to permit high dilutions of the specimens. In these high dilutions, salts other than calcium and magnesium did not interfere with the determination.

* Forty-eight hours before the second test dose of radioiron, J. L. received 1320 mg Fe as colloidal Fe(OH)₃ intravenously.

† The blood volume of J. L. and of S. W. was measured by the Evans blue dye method.

‡ H. N. vomited four hours after taking the test dose of radioiron.

Prior to October, 1946, the radioactive isotope used was Fe⁵⁹, prepared in the Washington University cyclotron. Since that time, we have used a mixture of Fe⁵⁹ and Fe⁵⁷ obtained from the Clinton Laboratories. On each day that determinations of radioactivity were made, the number of counts emitted by a standard prepared from the original iron solution was also determined several times; this value was used as the standard of reference for all calculations.

RESULTS

I. THE ACCURACY OF THE METHOD

Twelve recovery experiments were done to test the accuracy of the determination of radioactive iron in feces (table 1). In the first four, measured amounts of radio-

iron as ferric chloride were added to four different fecal suspensions which had been acidified with HCl. Because radioiron of weak activity was added to a large mass of feces in the first experiment, ether extraction according to the method previously described¹ was used, ether extraction was not done during any of the remaining determinations described in this report. In the next six experiments, the isotope in the form of ferric hydroxide, ferrous hydroxide, or ferric phosphate, was added to the fecal specimen, carefully mixed, and incubated at 37°C for twenty-four hours before the determination was made, in the last two experiments radioactive iron as ferric phosphate was added to the solid specimen and an excess

FIG. 1. RECOVERY OF AN ORAL DOSE OF RADIOIRON IN HYPOCHROMIC ANEMIA
 Dose, 1 mg Fe per kg as FeCl_2

of N NaOH was added. Recovery varied from 91 to 102 per cent, the form in which iron was added did not influence recovery.

Since iron-deficient subjects promptly and quantitatively utilize any iron available to them for hemoglobin synthesis,¹ it was thought that a study of iron absorption in such a group would provide a further means of checking the accuracy of the method. In these patients, if the method is valid, the sum of the radioiron found in the circulating blood and that recovered from the feces should equal the amount given orally in the test dose. Six experiments on patients with hypochromic microcytic anemia were done (table 2, fig. 1). In only one was the recovery less than 95 per cent, this patient vomited four hours after taking the test dose and failed to save the vomitus. It is possible that a small amount of the radioiron was lost in this way. In five experiments, from 95 to 110 per cent of the ingested isotope was recovered in the blood and feces.

These two types of observations define the accuracy of the method. The error

recovering iron from feces may be as great as 10 per cent. The sum of the amount found in circulating hemoglobin plus that recovered from the intestinal tract should not be in error by an amount greater than plus or minus 12 per cent.

2. NORMAL SUBJECTS

Absorption of radioiron was measured ten times in eight different normal subjects (table 3, fig. 2). The amount accounted for in blood and feces varied 83-100 per cent of the administered dose, in only two instances was the value less than 90 per cent. Comparison of the amount of radioiron retained by the body (activity in the test dose minus that recovered in the feces) with the amount found in circulating hemoglobin indicates that in 9 of the 10 determinations some iron was

§ G. G. vomited 6 hours after taking the radioiron.

|| The blood volume was determined by the Evans blue dye method.

absorbed but not utilized. Even though this quantity amounted to 17 per cent in the second experiment on J. T. and was 10 per cent or more in three other instances, it was never large. Because of the error of the method, it can only be stated that the results suggest that normal persons absorb more iron than they build into hemoglobin under these conditions.

There are, however, certain conclusions which can be made with assurance. Patients with hypochromic anemia do absorb several times more iron from test doses of this magnitude than do normal persons. On the other hand, normal subjects retain greater amounts than Hahn and his associates originally indicated might be the case.⁴ Even though the intestinal mucosa may be one of the principal regulators of iron metabolism as has been suggested, it is not so efficient a regulator that it causes normal subjects to reject iron almost completely.

In three of the experiments listed in table 3, a quantity of the iron-binding globulin of plasma, Cohn's fraction IV-7,* was given intravenously either before or after the oral test dose of iron. This was done to see whether absorption would be increased if considerable quantities of this globulin were circulating during the period of absorption. The differences were not great enough to justify any conclusion, if there was an increased absorption, the increase was certainly small.

3 PATIENTS WITH ANEMIAS OF VARIED ETIOLOGY OR FEVER

Iron absorption has been studied in 12 patients selected because they had diseases in which utilization of absorbed radioiron might well have been incomplete.

FIG. 2. RECOVERY OF AN ORAL DOSE OF RADIOIRON GIVEN TO NORMAL SUBJECTS
 Dose, 1 mg Fe per kg as FeCl_2

(table 4, figs 3, 4). We wished to know (1) how well these persons absorbed iron, and (2) how erroneous the results would have been if the amount of radioiron found in circulating hemoglobin had been taken as the sole measure of absorption. Because of the error in recovering iron from feces, no conclusions can be drawn from the results on patients 5, 10 and 12, even though the amount of radioiron found in their peripheral blood was negligible. For similar reasons, caution is necessary in interpreting the results on patient 6. Patient 12 might have shown greater absorption had she not had unusually rapid intestinal action. Over 60 per cent of the iron given appeared in a stool passed within eighteen hours of the dose. In the remaining observations, however, there is no question about the fact

* Obtained through the courtesy of Dr. E. J. Cohn.

that more iron was absorbed than could be accounted for in the hemoglobin of circulating blood. Experiments 8 and 9 demonstrate this particularly well. These two patients had Hodgkin's disease associated with fever and hypochromic anemia.

* Secondary hemosiderosis from many transfusions

On the basis of fecal recovery, they retained 52 and 32 per cent of the test dose, yet utilized only 15 and 2.5 per cent, respectively, to build hemoglobin.

Particular attention should be directed to the three observations on patients with pernicious anemia. The data for one of these experiments are graphically illustrated in figure 5. Shortly after administration of the test dose of radioiron, specific therapy in the form of liver extract was given. The radioactive isotope

FIG 6 Absorption of Radioactive Iron by a Patient with Pernicious Anemia

appeared slowly in this man's blood during a period of several months as he recovered from his anemia. If the observations had been stopped at ten days, it would have been concluded from measurement of isotopic hemoglobin that only 2 per cent of the test dose had been absorbed, yet 11 per cent eventually appeared in the blood. An even more dramatic result is illustrated in figure 6, data for this experiment are not included in table 4 because fecal recovery was not obtained. This patient had enough iron stored in his tissues to raise his hemoglobin from 7 to more than 12 grams per 100 cc. after specific therapy was begun, yet he absorbed more than 20 per cent of a test dose of radioiron. This fact was completely masked

FIG. 7. Absorption of Radioactive Iron by Patients with Pernicious Anemia

during the period of relapse and became evident only as he recovered from his anemia. Additional observations of a similar nature are recorded in figure 7. When the radioiron was given after therapy with liver extract, absorption was occasionally greater than during the pretherapy period.

Of particular interest also is the retention of over 20 per cent of the test dose by a patient with hemochromatosis while only 2 per cent appeared in his blood. Even if the fecal recovery was low by 10 per cent, he still absorbed five times as much as he built into hemoglobin. This man had diabetes, hepatomegaly, and bronzing of his skin. He had never received any transfusions to account for secondary hemosiderosis. The diagnosis was confirmed by biopsy of both liver and skin.

4. EFFECT OF LARGE DOSE OF INERT IRON GIVEN INTRAVENOUSLY ON ABSORPTION

To one of the patients with hypochromic anemia (J. L., table 2), 1345 mg. of inert iron as colloidal ferric hydroxide were given intravenously. This amount was

sufficient to increase his hemoglobin level from about 9 to over 12 grams per 100 cc. Twenty-one days prior to this injection, the patient absorbed 57 per cent of a standard test dose of radioiron (figure 8). Two days after the intravenous therapy, before he had converted much of the ferric hydroxide to hemoglobin and at a time when his tissues contained more than a gram of iron, he absorbed 24 per cent of a second test dose. Retention was less, therefore, after his tissues were well supplied with iron, but was still relatively large.

A similar result was obtained in another patient with hypochromic anemia, these data are not listed in table 2 because fecal recoveries were not done. This woman

FIG. 8 The Effect of a Large Dose of Parenterally Administered Iron on Iron Absorption

(A. D.), with a hemoglobin value of 9.4 Gm and a mean corpuscular hemoglobin concentration of 29 per cent, absorbed 60 per cent of a test dose of radioiron in a control experiment. Six weeks later she was given intravenously 755 mg of iron as colloidal ferric hydroxide. On the eleventh day after this procedure, when her hemoglobin had risen to 11.3 Gm and the mean corpuscular hemoglobin concentration was 30 per cent, she was given a second dose of radioiron. Of this, 27 per cent appeared in her blood as hemoglobin. Likewise, when 480 mg of iron as colloidal ferric hydroxide were injected into a dog with depleted iron stores, absorption was decreased from 14.9 per cent (control period) to 6.9 per cent. These results are at variance with those of Hahn and his associates⁸ who reported in one experiment that colloidal iron (304 mg) given by vein to an anemic dog did not significantly modify iron absorption.

In other experiments done on dogs made chronically anemic by regular phlebotomy, the authors have demonstrated that the level of iron in the serum has no apparent effect on iron absorption. If the serum iron level was raised above 500 mg per cent by intravenous administration of a soluble iron salt immediately before radioiron was given orally, absorption was not decreased (figure 9)

* Given 4 mgms. radio active iron per kilogram body weight (as ferrous chloride). (1,459,000 counts per hour)

FIG. 9 Effect of Iron in Blood Serum on Iron Absorption Radioactive Isotope Used

DISCUSSION

The results of these experiments indicate clearly that patients with impaired hemoglobin formation are capable of absorbing more iron than is used for hemoglobin synthesis. The data also suggest, but do not prove, that normal subjects may occasionally absorb more iron than is built immediately into hemoglobin. Caution must be exercised, therefore, in interpreting estimates of iron absorption obtained solely by measuring the per cent of a given test dose of radioiron which appears in the circulating blood as hemoglobin. Even when these limitations are

recognized, the isotope method is still the best one available for studies of iron absorption. Recovery of unabsorbed iron from feces, as was done in these studies, is too difficult and too time consuming to be practical. An error of approximately 10 per cent, furthermore, is involved in the recovery. If a study is to be made of the relative absorption from different iron salts, or of the effect of various influences like achlorhydria, food, the calcium-phosphorus ratio, etc., on iron absorption, the ideal procedure would be to use the isotope technic but to select only afebrile, iron-deficient patients as test subjects.

Objection might possibly be made to the experiments reported in this paper on the ground that one cannot be sure that a portion of the iron recovered in feces had not been absorbed and promptly excreted into the colon. There is abundant evidence, however, that the amounts of iron excreted into the gastrointestinal tract are minute.^{14 15} Any error introduced in this manner would be much less than the error of recovery per se and would be insignificant.

These results are of theoretic interest chiefly as they relate to the theory that the intestinal mucosa serves as a major regulator of iron metabolism.^{8 16 17} Granick has postulated the following explanation of absorption: the intestinal mucosal cells contain a protein, apoferritin, which combines with iron to form ferritin. The ferritin iron is thought to be in equilibrium with small amounts of ferrous ions in the cells, and the ferrous ions in turn are postulated as being in equilibrium with the iron in plasma. According to this concept, iron is taken up by mucosal cells until all the apoferritin is converted into ferritin. No more is absorbed until some of the ferritin has given up its iron to plasma. This theory explains beautifully the fact that iron-deficient subjects absorb more iron than do normal persons. It does not account adequately, however, for the equally clear demonstration that patients with pernicious anemia in relapse, with refractory anemia, or with hemolytic anemias may also absorb fairly large amounts of the metal even though their tissues are replete with iron. If the intestinal mucosa is a major regulator of iron metabolism, protecting the body from an uptake sufficiently great to cause toxic concentrations in the tissues, it at least is not as complete a regulator as it was first thought to be.

Many of the factors which control iron absorption are unquestionably still unknown. In unpublished experiments, the authors have confirmed Hahn's observations that anemia by itself does not influence iron absorption. Uptake from the intestinal tract has been shown to be independent of the plasma iron concentration. On the other hand, if tissue iron reserves of subjects with hypochromic anemia are partially restored by the parenteral administration of large amounts of iron, uptake of the metal from the alimentary tract becomes less complete. The possibility has been explored that a factor may be present in the blood of iron-deficient subjects which stimulates absorption, but in two unpublished experiments the infusion of large amounts of plasma from iron-deficient into normal dogs has failed to affect the quantity absorbed. The mucosal block theory of Hahn and Granick remains the best explanation for all the known facts about iron absorption, but the 'block' should be thought of in relative terms.

SUMMARY AND CONCLUSIONS

- 1 The isotope technic for studying iron absorption has been extended to measure the unabsorbed isotope in feces as well as the amount synthesized into hemoglobin. The recovery of radioiron from feces was shown to be accurate within 10 per cent.
- 2 There was suggestive evidence to indicate that, with the 1 mg per kilogram dose employed, normal subjects may sometimes absorb more iron than is converted within a two week period into hemoglobin.
- 3 Patients with fever, untreated pernicious anemia, and refractory anemia were shown to absorb more iron than they use for hemoglobin.
- 4 Patients with hemolytic anemia may absorb more iron than can be recovered in the peripheral blood at any one time because isotopic hemoglobin is removed from the circulation at a rapid rate.
- 5 Except in afebrile patients with hypochromic anemia, acceptance of the per cent of a given dose of radioiron which appears in circulating hemoglobin as a measure of iron absorption must be made with caution.
- 6 The theory that mucosal cells accept iron for absorption or block its assimilation provides the best known explanation for iron absorption, but patients with adequate iron stores may assimilate considerable quantities of the metal and the block must be regarded as relative.

OSMOMETRIC BEHAVIOR OF NORMAL AND ABNORMAL HUMAN ERYTHROCYTES

By GEORGE M. GUEST, M.D.

VARIOUS investigators have postulated two main principles which seem to govern the swelling and hemolysis of red blood cells suspended in hypotonic salt solutions—namely, the cells imbibe water according to the laws of osmosis, and their maximum swelling is limited by an inelastic surface membrane. According to this concept, hemolysis occurs when the erythrocytes in hypotonic solutions attain a critical volume at which the cells rupture and allow hemoglobin to escape. Studies of the physico-chemical mechanisms involved in the processes of osmotic swelling and hemolysis of erythrocytes have involved a great deal of controversy, especially over the question of whether the mammalian red cell behaves as a 'perfect osmometer,' adapting itself to changes in osmotic pressure of surrounding fluids by the transfer of water alone (Ponder¹⁸). Evidence assembled by Ponder¹⁹ from many sources indicates that the erythrocytes of various species sometimes do behave as perfect osmometers, but at other times and under varying conditions they behave as decidedly imperfect osmometers. The reasons for this variable behavior are still obscure.

Methods devised for the measurement of the osmotic fragility of red cells have had clinical applications especially valuable in the diagnosis of congenital hemolytic jaundice and in the differential diagnosis of other types of hemolytic disease. The first development of such a method is generally ascribed to Hamburger¹⁰ who in 1883 devised a test that involved the notation of 'beginning' hemolysis and 'complete' or total hemolysis, or the points of minimal and maximal resistance of red cells suspended in a series of solutions of diminishing concentrations of sodium chloride. Jolly¹⁶ states that even earlier, in 1880, Chancel² described a method for measuring red cell fragility in hypotonic salt solutions and applied it in clinical studies. It is of interest to note that Chancel's was a quantitative test, in contrast to the essentially qualitative test of Hamburger. According to Jolly, Chancel made suspensions of blood cells in a series of salt solutions of diminishing concentrations and after a given time determined the number of cells destroyed by counting the intact cells. By this method he demonstrated diminished osmotic resistance of erythrocytes in certain anemias and increased resistance in certain types of jaundice. Whitby and Hynes²⁴ independently developed approximately the same procedure in 1935. Several refinements of Hamburger's procedure have been suggested to disclose minor differences in cell fragility that characterize certain pathologic types of red cells (Wintrobe^{25a}), but the noteworthy advances in methodology are mainly confined to quantitative measurements of hemolysis. Estimations of the degree of hemolysis at each point in the hemolytic series have

From the Children's Hospital Research Foundation and the Department of Pediatrics, University of Cincinnati, College of Medicine, Cincinnati.

With the Technical Assistance of Mary E. Wing, M.S. Miss Wing died April 5, 1947.

been made by determinations of the hemoglobin liberated from the erythrocyte into the suspension fluids by visual colorimetry^{1 11} and by more accurate photoelectric colorimetry^{12 23}

Various technics have been employed for demonstrating the swelling, or osmometric behavior, of various species of red cells in hypotonic fluids determinations of cell volume have been made by centrifugation, employing several types of hematocrit apparatus, and by electrical conductivity measurements, estimations of mean cell diameters have been made by diffraction methods and by measurements of projected images of the cells, sometimes with photography (Ponder¹⁷⁻²¹) Another approach to this study is by kinetic methods (Jacobs, et al ¹³⁻¹⁵) whereby the rate of hemolysis of red cells is determined, within periods of a few seconds, in hypotonic solutions at the critical tonicities, or less, that produce complete hemolysis Such technics have been used rarely if at all in clinical studies of abnormal types of erythrocytes

Seeking a practical method for studying the osmometric behavior of red cells in clinical investigations, Guest and Wing⁵ at first employed standard Van Allen hematocrit tubes²² in which blood was diluted in the usual series of salt solutions After centrifugation the volume of packed cells, measured in the graduated stems of the pipets, afforded an estimate of the swelling of the cells that occurred before hemolysis, and the progress of hemolysis at lower tonicities was judged by the diminishing mass of cells as well as by the color of the fluid in the bulbs of successive pipets A later elaboration of that procedure⁶ combined the quantitative determination of hemolysis with measurements of the volume of cells at each stage of the test Observations made by this method on the erythrocytes of normal adults, children and newborn infants indicated that the swelling of these normal human red cells in every instance followed closely that expected in perfect osmometers Moreover, the maximum volumes attained by the normal cells before hemolysis agreed closely with predictions based on estimations of their mean surface area, thus supporting the view that the red cell cannot distend beyond the limit set by its surface area The present paper reports further data, gathered by that method, on the erythrocytes of normal subjects and on the erythrocytes of patients suffering several diseases in which abnormal fragility of red cells is commonly found

METHOD

Only the main steps of the procedure and the principal calculations employed need be given here, further details may be found in the paper by Guest and Wing ⁶ The special Van Allen pipet with elongated bulb devised for this method is calibrated to contain 8.0 cc when filled to the upper mark, and to contain 0.02 cc in the graduated portion of the stem marked with 100 divisions Twelve or 15 pipets are usually used in each test Heparinized blood is drawn into the stem to the 100 mark and after it the appropriate solution of NaCl is drawn into the pipet almost to fill the bulb, leaving a small air bubble to facilitate mixing the fluid and blood The usual series of salt solutions is employed, beginning with 0.9 per cent NaCl, with decrements in concentrations 0.1 or 0.05 per cent before the beginning of hemolysis and 0.025 per cent through the expected critical range of hemolysis The tip of each pipet is then sealed with a rubber cushioned spring clip and the pipets are left resting in a horizontal position at room temperature an hour, after which they are centrifuged 20 minutes at 2500 to 3000 r p m, and the volume of packed cells is read in per cent on the graduated stem The bulb is then filled to the 8.0 cc mark with distilled water (making the dilution of blood 1:400), the fluid is transferred by means of a long stemmed

pipet to colorimeter tubes, and the hemoglobin content of each fluid is read in a photoelectric colorimeter.³ The total hemoglobin content of the blood is determined on a separate sample measured into distilled water, with a drop of ammonium hydroxide added to insure complete hemolysis and absence of turbidity. The hemoglobin content of each supernatant fluid in the series is then expressed in per cent of the total hemoglobin, indicating the per cent hemolysis found at each tonicity. Further calculations are made to compare the observed cell volumes with the expected osmometric swelling at each tonicity and to predict the maximum swelling expected if the cells attain the volume of spheres within the limits of their estimated mean surface area.

TABLE 1—*Hemolysis and changes in volume of normal erythrocytes of blood diluted 1:400 in solutions of sodium chloride. Normal child, S. S.*

These data are presented graphically in figure 1.

* Volume of a perfect osmometer, in per cent of its initial volume, assuming the initial water content to be 70 per cent by volume.

† R value is the ratio, observed cell volume (corrected for hemolysis) to the expected osmometric volume.

‡ Values in per cent of the initial volume of the cells in 0.9 per cent NaCl solution.

Data thus determined on a sample of normal blood are presented in table 1. Column 1 indicates the tonicities at which the readings of hemolysis, listed in column 2, and of cell volume, listed in column 3, were made. In column 4 the values for cell volume at the respective tonicities are converted to percentages of the initial volume as read in the 0.9 per cent NaCl solution, and in column 5 these values in turn are corrected for hemolysis (employing the values in column 2) to indicate the true volume, or swelling, of the cells remaining intact in the tubes where partial hemolysis occurred. The values for expected osmometric volume, given in column 6, are based on the formula of Ponder¹⁰ $V = W(1 - T) + 100$, where V = the new volume of the cells in per cent of their initial volume, W = the percentage by volume of water in the cells, taken as 70 per cent, T = the ratio of the tonicity of

the medium to 0.9 per cent NaCl solution (i.e., with 0.45 per cent NaCl, $T = 0.5$), 100 = the initial volume of the cells. In the last column the "R values" represent

* Volume of a perfect osmometer, in per cent of its initial volume, assuming the initial water content to be 70 per cent by volume

† Values in per cent of the initial volume of cells in 0.9 per cent NaCl solution

R values represent the average for all points in the series up to the tonicity indicated, other values are for the one point indicated e.g., for the patient R. G., with hypochromic anemia the average of R values for tonicities 0.8 to 0.75 per cent NaCl was 1.00 but at 0.75 per cent maximal swelling of the cells occurred, the R value was 0.80

finding discrepancies between observed volumes and expected volumes of cells at different tonicities, when some erythrocytes did not behave as perfect osmometers. Where the observed swelling agrees with that calculated from the formula, with the water content of the cells assumed to be 70 per cent, the R value is 1.00. The R values at different points in the series range between 0.95 and 1.02, a degree of variability that may be regarded as approximately the experimental error of the method.

Values for the mean volume of the cells in the undiluted heparinized blood were calculated as usual from the hematocrit measurement⁶ and the cell count, and the

Hemolysis and changes in volume of erythrocytes in hypotonic salt solutions: (1) Hemolysis, expressed in per cent of the total hemoglobin in the sample, (2) Observed cell volume, per cent of the initial volume of the cells in 0.9 per cent NaCl solution, (3) Cell volumes corrected for hemolysis, i.e., the volume of the unhemolyzed cells, (4) Expected maximal cell volume calculated from the mean surface area, (5) Expected osmometric volume of the cells at different tonicities, assuming the initial water content of the cells to be 70 per cent. Data on this blood are listed in table 1.

mean diameter of the cells was read from stained films by means of the Haden-Hauser erythrocytometer.¹¹ The mean thickness (T) was calculated from the mean volume and diameter ($T = V/\pi r^2$). The mean surface area was calculated as that of a flat disc of the same thickness and diameter. The expected maximal swelling was calculated as the percentile relationship of the volume of a sphere with the same surface area to the initial mean volume of the cells, i.e., the percentile swelling expected if the cells attain their maximal volume as spheres within the limits of their mean surface area, following essentially the steps suggested by Haden.^{7,8}

OBSERVATIONS

Several different patterns of osmotic behavior of human erythrocytes are illustrated by examples cited in the accompanying tables and figures, which are set

lected from a large series of studies that were made during the years 1939 to 1943 with the assistance of Miss Mary Wing Presumably normal red cells from healthy

For explanation of symbols see figure 1

subjects are represented in tables 1 and 2 and figure 1, abnormal types of cells are represented in table 3 and in figures 2 to 7

Normal subjects Observations on the blood of a normal child, S S are illustrated by figure 1, and by data listed in table 1 and in table 2, example 17. In the figure, curves 2 and 3 show how the swelling of the cells before and after the point

of beginning hemolysis (curve 1) followed closely the expected osmometric volume (curve 5) at each tonicity, to reach exactly the expected maximal cell volume (horizontal line 4) predicted from the mean surface area calculated from the measurements of initial dimensions

For explanation of symbols see figure 1

FIG 5 SICKLEMLIA IN A NEGRO BOY, M. J. W., 10 YEARS OF AGE

For explanation of symbols see figure 1

In table 2 data on the erythrocytes of normal subjects, adults, children and newborn infants, are arranged to show how normal cells, though varying considerably in their dimensions of mean volume, diameter and thickness, conform closely to the pattern of behavior illustrated in figure 1. Normal erythrocytes usually attain a maximal volume of from 170 to 175 per cent of their initial volume, and this degree

of swelling is found most often in about 0.425 per cent NaCl solution. The R values in table 2 represent the average of all values determined in the series for each blood up to the point of maximal swelling. Among the bloods from adults and

children listed, the deviations of the R values from the theoretically expected value of 1.00 are scarcely more than can be ascribed to experimental error. It is to be noted that the R values for the macrocytic cells of newborn infants were consistently slightly low, around 0.95, but the observed maximal swelling agreed closely with the values, around 165 per cent, predicted from the mean surface area

Congenital spherocytosis Figure 2 illustrates diagrammatically the osmometric behavior of the erythrocytes of a 4 year old boy (sample J J, in table 3) suffering typical manifestations of congenital hemolytic jaundice. Hemolysis of these cells began in 0.8 per cent NaCl solution and appeared to be complete, with cellular residue too low to be read, in 0.45 per cent solution (although the hemoglobin liberated in this solution represented only 85 per cent hemolysis). The swelling of the unhemolyzed cells followed fairly closely the expected osmometric volume, and reached exactly the calculated maximum volume, 152 per cent of the initial cell volume.

In table 3 are listed data on ten samples of bloods from patients suffering congenital hemolytic jaundice. Hemolysis of the cells in these bloods began in solution of NaCl varying from 0.85 to 0.65 per cent, and in all instances appeared to be complete (by visual inspection) in solutions around 0.40 per cent. Except for the last sample listed, the maximum swelling of these erythrocytes was between 128 and 156 per cent of their initial volume. The last two samples listed, from the patient W M, were drawn respectively before and two weeks after splenectomy. A great improvement in the patient's general condition was observed after splenectomy. The postoperative blood sample showed lessened red-cell fragility as indicated by the point of beginning hemolysis and by greater maximum swelling, compared with that of the sample drawn before operation. In all instances the maximum swelling was predicted fairly closely from the mean surface area of the cells, and the *R*-values were about the same (within limits of experimental error) as those of normal erythrocytes at all tonicities up to the point of maximal swelling.

Hypochromic anemia In studies on patients with varying degrees of anemia presumed to be due to simple iron deficiency, different patterns of osmotic behavior of the red cells were found among bloods showing varying degrees of hypochromia and microcytosis. The first example in this group, cited in table 3 and figure 3, was a blood sample from a Negro woman, F D, with mild anemia, with hemoglobin concentrations in the whole blood 9.9 grams and in the packed cells 30 grams per 100 cc, and the mean cell volume 75 cubic microns. The unusually high value for maximal swelling of these cells, 199 per cent of their initial volume, agreed closely with the predicted value and the swelling followed very closely the expected osmometric swelling up to the maximal point, with an average *R*-value 1.00. In the last three examples cited in this group, R G, D P, L W, with cells showing a greater degree of microcytosis and hypochromia, the swelling of the cells followed the expected osmometric volumes up to a certain point, in each case after the beginning of hemolysis, but thereafter the swelling of the remaining cells was less than expected (*R*-values at first 1.00, then 0.80 to 0.91) and the maximum volumes attained were less than the values predicted from the mean surface area.

Thalassemia The first of the two sets of data listed under thalassemia in table 3 and illustrated in figure 4 concern the erythrocytes of a 15 year old boy, G B, who exhibited typical manifestations of Mediterranean or Cooley's anemia, with large spleen, moderate skeletal changes, moderate anemia and normoblastemia. The red cells were moderately large in mean volume and diameter, but thinner than normal. There was the usual wide span of osmotic resistance, with hemolysis beginning at

0.5 and not complete until around 0.1 per cent NaCl. At all tonicities the observed swelling was less than the expected osmometric swelling, with the R-value gradually diminishing, from 0.88 to 0.81, but the final maximal volume of 213 per cent approached closely the value predicted from the mean surface area. The second set of data listed in the table relate to this boy's brother, J. B., who showed no physical manifestations of this disorder but whose blood showed the typical target cells and microcytosis such as have been noted by several investigators^{25b} among essentially healthy members of the families of patients suffering with Cooley's disease. These cells were small and thin, they too had a rather wide span of resistance, but their swelling followed closely the normal expected pattern up to a maximum volume of 199 per cent, with behavior like that observed in the case of F. D., illustrated in figure 3, with mild hypochromic microcytic anemia. Two other siblings in this family had mild anemia that did not respond to the administration of iron, with microcytic hypochromic erythrocytes and target cells like those of the blood of J. B. and displaying similar osmotic behavior. Apparently the defect responsible for poor osmometric behavior in the cells of the patient, G. B., was not present in the cells of the siblings, although the microcytes and target cells in such families have been regarded as part of the genetic picture of thalassemia.

Sickleemia The two patients, M. J. W. and M. W., represented in figures 5 and 6, respectively, displayed noteworthy differences in symptomatology as well as differences in the osmotic behavior of their red cells. The first, M. J. W., represented in figure 5, had experienced little illness, was not known to have had crises of anemia or jaundice at any time, and the spleen was not palpable. Sickling of his cells in a sealed cover glass preparation occurred quickly and involved practically 100 per cent of the cells. The other, represented in figure 6, had suffered repeated crises of abdominal pain associated with anemia, slight jaundice, and enlargement of the spleen. Sickling in his blood occurred rather slowly and involved about half of the cells in a sealed cover glass preparation allowed to stand twenty-four hours at room temperature. Reticulocytes in the two bloods were respectively 2.6 and 11.2 per cent. The erythrocytes of both bloods were thinner than normal (see data in table 3). The swelling of the cells in both bloods at all tonicities was considerably less than the expected osmometric swelling. The cells represented in figure 5 attained a maximum volume close to that predicted from the surface area, but in figure 6 the observed maximal volume is seen falling far below the predicted value. Figure 5 shows a considerably increased osmotic resistance, with only slight hemolysis appearing at tonicities from 0.45 to 0.35 per cent NaCl and complete hemolysis at around 0.125 per cent. Figure 6 shows a diminished resistance of part of the cells, with hemolysis beginning in 0.6 per cent NaCl solution and complete at around 0.225 per cent. Data on the red cells of a third patient (subject E. J.) with sickleemia cited in table 3 resemble those of the subject M. J. W. in that the R-values were consistently low but the observed maximal volume agreed closely with the predicted maximal volume.

Pernicious anemia Observations on the erythrocytes of a patient, J. W., suffering from pernicious anemia are illustrated in figure 7, other data on these cells are

listed in table 3. This sample of blood was obtained when the reticulocyte count was 25 per cent, following the administration of liver extract. The erythrocytes were typically large in all dimensions, their swelling at all tonicities was less than the expected osmometric swelling, and the maximal volume found was considerably less than predicted from the mean surface area. These observations are presented not to suggest that such findings are necessarily typical of pernicious anemia (further observations on other patients are lacking) but to illustrate again a pattern of abnormal behavior found in red cells of pathologic type.

Miscellaneous. Normal osmotic behavior of erythrocytes, corresponding closely to that illustrated in figure 1, has been found in cases of polycythemia vera, cirrhosis of the liver, anemia associated with acute and chronic nephritis, liponephrosis and other metabolic diseases.

DISCUSSION

These observations indicate that normal human erythrocytes, and also some abnormal types of red cells varying considerably in size, shape and hemoglobin content, display a remarkably uniform pattern of osmotic behavior in hypotonic salt solutions, swelling like perfect osmometers up to a maximum volume of spheres within the limits of their surface areas. Contrasting pictures may be seen in studies of the thick cells, spherocytes, of congenital hemolytic icterus and the thin cells of mild hypochromic anemia as illustrated in figures 2 and 3 respectively. The patterns of behavior exhibited by the two types of cells appear to be governed by fundamentally similar principles, although their relative "fragility" appears to be quite different. The abnormal fragility of the cells of congenital hemolytic icterus probably depends on the character of the internal structure of the cell that is responsible for their greater than normal thickness rather than on any abnormality of the surface membrane affecting its permeability or susceptibility to stress.

The well known increased resistance, or decreased fragility, of the red cells of thalassemia, indicated by the points of beginning and complete hemolysis in the Hamburger series, can be explained by two mechanisms demonstrated in figure 4. First, the cells behave as poor osmometers, swelling less than expected at all tonicities, and second, the very thin cells of large diameter are capable of much greater percentile swelling than normal cells within the limits of their surface area. Such explanation applies also to the somewhat increased osmotic resistance of the cells of the patient with sickle cell anemia, represented in figure 5.

The red cells in all three cases of sickle cell anemia cited in table 3 behaved as poor osmometers, swelling less than expected at all tonicities. The span of hemolysis was wide in each instance. In two cases the observed maximal swelling of the cells agreed closely with the value predicted from the mean surface area, but in the case of M. W. (fig. 6), the observed maximal swelling was much less than predicted. It seems possible that the patients represent distinctly different clinical types, one showing merely the sickling trait with increased resistance of the cells, and the other a more complicated picture of a hemolytic type of anemia with increased fragility of at least a part of the red cells. The patient M. W. displayed

symptoms and physical manifestations, with crises of jaundice, anemia, and enlargement of the spleen, compatible with this concept. There is of course the possibility that a hemolytic trait may be superimposed on the sickling trait.

Investigators who have found erythrocytes swelling less in hypotonic fluids than should be expected if they imbibe water like perfect osmometers have offered several explanations for this behavior: namely, (1) that salts escape from the cells in the course of their swelling, not necessarily at a constant rate nor reaching the same equilibria at different tonicities, (2) that variations in the water content of the cells may be large, so that the formula for osmometric swelling, based on an assumed initial water content of 70 per cent, cannot be applied to all erythrocytes alike, (3) that some of the water in the cells is "bound" to hemoglobin and other constituents and is not transferrable by osmosis, (4) that phenomena of gelation in some cells may lead to physical conditions quite unlike those assumed for a simple sac or envelope containing hemoglobin and other osmotically active substances in solution.^{19, 21}

It would appear that any one or several of these explanations might apply to the osmotic behavior of abnormal types of erythrocytes such as are cited here. It is well to note, with regard to seemingly contradictory statements of various investigators regarding the osmotic behavior of "the erythrocyte," that generalizations are not sound when they imply (as some have) that observations on the red cells of one or a few members of a species can be applied to all individuals of the species or to other species. It must be borne in mind that erythrocytes of different species differ considerably in their characteristics of osmotic fragility, also, that differences in osmotic behavior of red cells drawn from the same individual at different times may arise from alterations in cellular composition and metabolic activities induced by various pathologic conditions, which may not be readily apparent and may even be transient.*

SUMMARY

Normal human erythrocytes suspended in the series of hypotonic salt solutions employed for testing red cell fragility behave like nearly perfect osmometers throughout the series, with their maximum swelling, usually around 175 per cent of their initial volume, sharply defined by their mean surface area. The same principles govern the swelling and hemolysis of some abnormal types of erythrocytes with different characteristics of abnormal fragility or resistance to osmotic hemolysis. The red cells of congenital hemolytic icterus exhibit essentially normal osmotic behavior, but since the spherocytes can swell very little within the limits of their surface area they rupture at higher tonicities, with the maximal swelling in most instances around 150 per cent of their initial volume. Thin cells are capable of greater swelling than normal cells. Moderately hypochromic erythrocytes from patients with mild anemia behaved like perfect osmometers throughout the series,

* The effects of environmental factors, e g, anticoagulants, diluting fluids, time of preservation, temperature, etc., on erythrocytes prior to studies of their osmotic behavior have been thoroughly discussed in several papers of the symposium on blood preservation recently published in the *J. Clin. Investigation*, 26: 591-755, July 1947.

to attain a maximal swelling of around 200 per cent, this value agreeing with predictions based on their mean surface area

Erythrocytes of patients with thalassemia, sickle cell anemia and pernicious anemia exhibited less than the expected osmometric swelling throughout the series of hypotonic solutions. The cells behaving as imperfect osmometers displayed varying patterns of hemolysis, and of maximal swelling in relation to predicted values. The increased osmotic resistance characteristic of the cells of thalassemia is accounted for by two mechanisms: they swell less than normal cells at each tonicity, and, being thin, they undergo greater swelling (around 220 per cent) before they are hemolyzed.

A METHOD FOR DETERMINING THE FORM OF THE DISTRIBUTION OF RED CELL RESISTANCES TO SIMPLE HEMOLYSINS

By ERIC PONDER, M D , D Sc

THE DETERMINATION of the way in which the resistances of red cells are distributed with respect to hypotonicity (the erythrocyte fragility test) is a familiar laboratory procedure, and methods have been described for finding the distribution of the resistances of red cells to heat,^{1 2} to acid,³ to shaking,^{4 5 6} to saponin hemolysis^{7 8} and to hemolysis by lysolecithin.⁹ It is now recognized that the form of the frequency distribution of red cell resistances to hypotonicity is determined primarily by the variations in the shape of the cells of the system,¹⁰⁻ and it is reasonable to think that the forms of the frequency distributions of resistances to lysins such as saponin or digitonin depend on the chemical nature and spatial arrangement of the components of the red cell architecture, i.e., on the "consist"* of the cell or of its surface ultrastructure. Just as it is necessary to have a method by means of which fragility can be described quantitatively before its relation to shape can be appreciated, so it is necessary to have a method by means of which the distribution of resistances to lysins can be described quantitatively before it is possible to study the relation of the resistance to chemical composition, spatial arrangement, etc.

The purpose of this paper is to describe a method for measuring the resistance of red cells to simple hemolysins, to define the range of normal variation, and to give a few illustrations of abnormal variations in resistance which occur under conditions in which it is reasonable to believe that abnormal variations in the consist of the members of the cell population have occurred. Emphasis will be placed on the observations being made and treated so that the maximum amount of information can be extracted from them, because the full potentialities of methods for determining red cell resistances are not realized when they are carried out in simplified form. Further, it should be remarked at the outset that the method to be described is of general application, although it is illustrated by results obtained with only two simple hemolysins, in addition to the results of fragility determinations.

I COMPOSITION OF THE HEMOLYTIC SYSTEMS

To illustrate the procedure, the two lysins saponin and digitonin have been selected for several reasons. More is known about the kinetics of lysis by saponin than by any other lysin, and the flat form of the frequency distribution of resistances makes it particularly useful for picking up bimodalities, etc. Digitonin is selected because it is one of the few powerful lysins which can be obtained in the pure state (unlike the saponins, the activity of which is variable), and free from inhibitory contaminants (unlike most preparations of the bile salts).

(a) *Saponin* Add 10 mg of quillia saponin (British Drug Houses) to 100 ml of 1 per cent NaCl,

From The Nassau Hospital, Mineola, N Y

* This is a noun, the general use of which has been urged by Schlegel¹⁷, it is employed in describing the composition of railway trains. Its definition is "Consist," "The singular elements of which something is constituted together with all the relevant spatial arrangements of these elements." As Schlegel points out, there is no other word in our language which conveys quite the same idea.

this gives 1:1 in 10,000, or a 200 γ /2 ml solution of the lysin. A series of dilutions is made from this, so that 100 ml volumes of a series of solutions of saponin containing 100, 80, 60, 50, 40, 30, 25, 20, 15, 12, 10, 8, 6, 4, 3, 2, and 1 γ per 2 ml are obtained. The solutions are stored in stoppered bottles at temperature 4 C, and keep for about 1 month.

(b) *Digitonin* 100 ml volumes of solutions of digitonin (Merck) in 1 per cent NaCl, and containing 20, 17.5, 15, 12.5, 11.25, 10, 8.75, 7.5, 6.25, 5.0, 3.75, 2.5, and 1.25 γ per 2 ml are prepared. Because of the steepness of the digitonin percentage hemolysis curve, intermediate concentrations, e.g., 8.125 γ /2 ml, may be needed, if so, 2 ml of such a concentration can be made by mixing 1 ml of the concentrations above it and below it in the series, i.e., 8.75 γ /2 ml and 7.5 γ /2 ml. As the final values for hemolysis are reached within fifteen to thirty minutes in systems containing digitonin, the need for making additional observations at such intermediate concentrations can be appreciated soon after the experiment is set up, systems containing the intermediate concentrations can then be added if necessary, and the results can still be read at the end of 5 hours without any error having been introduced. The digitonin solutions keep at 4 C for about 1 month.

(c) *Hypotonic NaCl* A series of solutions of hypotonic NaCl is prepared,* starting with a 0.5 per cent NaCl and descending by a common difference of 0.02 units, i.e., 0.50, 0.48, 0.46, ... per cent NaCl, in the scale of tonicity (the tonicity of a 1 per cent NaCl corresponds to 1 tonicity unit). The lowest member of the series should be 0.14 per cent NaCl. These solutions are stored at 4 C. When 0.5 ml of a red cell suspension, with a tonicity of 1.0, is added to 2 ml of each member of the series, we get a new series for the final tonicity T_1 of the mixture, this is

$$T_1 = \frac{2T_0 + 0.5}{2.5}$$

where T_0 is the tonicity of the member of the first series. The common difference on the new series for the final tonicity is 0.016, so that the new series runs 0.60, 0.584, 0.568, ... with a lowest member of 0.312 per cent NaCl or tonicity units. For convenience in differentiating the experimental curves, the members of the new series can be described by integers starting with 0.60 = 0, so that 0.584 = 1, 0.568 = 2, 0.312 = 18, as in the subsidiary scale on the abscissa of the curve marked T in figure 2.

(d) *Cell suspensions* The volume concentration ρ of the red cells in freshly drawn heparinized blood is found with a high speed hematocrit, and the cells of 2.5 (0.4/ ρ) ml of blood, after being washed three times with 1 per cent NaCl, are finally suspended in 25 ml of NaCl-buffer at pH 7.0 †

(e) *The hemolytic systems* The hemolytic systems, contained in three series of 100 \times 13 mm tubes, are prepared by adding 0.5 ml of the red cell suspension to 2 ml volumes of the various concentrations of saponin, digitonin, and hypotonic NaCl. The lysins are put into the tubes first, and allowed to reach the temperature at which the determinations are to be made, 0.5 ml of suspension is then added to each tube, with immediate shaking to produce mixing. Any desired temperature can be obtained by using water

* The NaCl used must be silver-free,¹⁸ as most C.P. preparations now are. It must also be dry. Commercial preparations may contain as much as 10 per cent of water after standing around the laboratory, they should be dried for twenty-four hours at 120 C before use.

† The NaCl-buffer is made by mixing 75 ml of 1.2 Gm/100 ml NaCl with 25 ml of a mixed buffer composed of 72 ml of M/15 Na_2HPO_4 and 28 ml of M/15 NaH_2PO_4 . The depression of freezing point of this NaCl-buffer is the same as that of 1 Gm/100 ml NaCl (i.e., its tonicity is 1.0), and its pH is 7.0 at 25 C.

The pH of the systems requires to be controlled at a known value because the activity of many lysins, e.g., saponin and the bile salts, has a marked pH dependence. It is usual to make measurements of fragility in systems containing unbuffered hypotonic NaCl on the grounds that the situation may be complicated by the addition of the ions in the buffer mixtures. This is true, but the situation is also liable to be complicated by uncontrolled variations in pH, especially if the red cell suspension is dilute.¹⁹ If the suspension is more concentrated, the effects may be very much less,²⁰ but, since a complete investigation of the distributions of resistances to simple lysins and to hypotonicity would include measurements of resistances at a variety of pH's, one may as well buffer the systems from the start.

baths, but 25 C is a convenient temperature which can easily be maintained to within ± 1 C for five hours at a time in the average laboratory room

The hemolytic systems are mixed, either by rotary shaking or by inversion, every fifteen minutes, and the amount of hemolysis in each is determined at the end of five hours

2. MEASUREMENT OF PERCENTAGE HEMOLYSIS

To find the percentage of complete hemolysis present in any one of the hemolytic systems at the end of five hours at 25 C, the cells are thrown down by spinning for a few minutes at 2000 r p m. The supernatant fluid can then be poured off into a dry vial without disturbing the cells. Two ml of this supernatant fluid is added to 10 ml of distilled water, and the optical density is measured at a wave length of about 4500 Å (blue filter) with a Lumetron photometer or with any other photometer of a similar type. This measurement is converted into a value for percentage

FIG. 1. DIAGRAM TO ILLUSTRATE THE METHOD OF GRAPHIC DIFFERENTIATION
For description, see text

hemolysis by referring to a calibration curve, prepared by measuring the optical densities corresponding to 100, 50, 25, and 12.5 per cent of complete hemolysis of the cells contained in the hemolytic systems. When measured at 4500 Å, the optical density is so related to the concentration of Hb present that percentages of complete hemolysis are found with about the same degree of accuracy over the whole percentage hemolysis range.

A separate calibration curve must be prepared for each suspension used, in practice, one uses the pooled contents of several completely hemolyzed systems for obtaining the 100 per cent point, and finds the other points by successive dilutions by powers of 2.

3. PLOTTING AND DIFFERENTIATION OF THE CURVES

The values of percentage hemolysis P are plotted against the quantity of lysin in γ contained in the system, using the same scales for ordinates and abscissae as those used in figures 2, 3, and 4. The choice of the scales is important, as it de-

termines the ease and accuracy with which differentiation can be carried out. Smooth sigmoid curves are drawn through the experimental points, a possible error of about ± 2 per cent being allowed in the case of each. If inspection shows that the curve is bimodal or polymodal, the procedure is still to draw the smoothest curve through the experimental points. It will be obvious that the more points

FIG. 2. NORMAL FREQUENCY DISTRIBUTIONS OF RESISTANCES, TOGETHER WITH THEIR INTEGRALS (THE EXPERIMENTAL CURVES)

Ordinates, percentage of complete hemolysis, abscissae, quantity of lysin in system in γ except in curve T, where the abscissa shows the tonicity in tonicity units. Subsidiary scale on abscissa of curve T is that used in differentiating. Curve S, results for saponin, curve D, results for digitonin, curve T, results for hypotonic NaCl. Reduction, $2\times$

there are, the more certainly can the course of the curve be determined, and in some cases of suspected polymodality it may be necessary to repeat the entire set of determinations with the addition of new and strategically placed concentrations of the lysin.

The sigmoid curve is now differentiated graphically by using the following principle. If TT' is the tangent at a point P with coordinates x and y (fig. 1), and if OA , the parallel through the origin, cuts the ordinate of P at y' , the value of

dy/dx at the point P is $y'' = y'/x$. Proceeding along the sigmoid curve systematically, tangents and their parallels through the origin are drawn with the aid of rulers fixed so as to move in parallel, these can be purchased from any dealer in draughtsman's materials. The value of y' (read off on the ordinate) at which the parallel through the origin cuts the ordinate of the point under consideration is noted and is divided by the value for the x-coordinate of the point (read off on the

FIG 3 FREQUENCY DISTRIBUTIONS AND THEIR INTEGRALS FOLLOWING MASSIVE HEMORRHAGE

Ordinates, abscissae, etc., as in fig 1

abscissa), the result of the division is a value of y'' , the ordinate of the corresponding point on the differential curve. To change the scale on which the differential curve is plotted, the value of y' can be divided, not by x , but by x/s , where s is a convenient scaling constant, the values $s = 10$ for saponin, $s = 1$ for digitonin, and $s = 2$ for hypotonic NaCl are convenient because the frequency distributions are then plotted on such a scale that their shape and variations in it can be easily appreciated by eye. These values have been used in constructing the differential curves in figures 2, 3, and 4. If $s = 1$ were used for saponin, for example, the differential curve would be so flat that variations in its shape would not be apparent on simple inspection.

This process of differentiation can be carried out quickly and easily, and is all done on the same piece of graph paper. The number of tangents which require to be drawn depends to some extent on the shape of the sigmoid curve, but one should be drawn at each experimental point for a start. The process is completed by drawing a smooth curve through the points y'' obtained by differentiation. In each case, the result is a frequency curve showing the distribution of red cell resistances to the

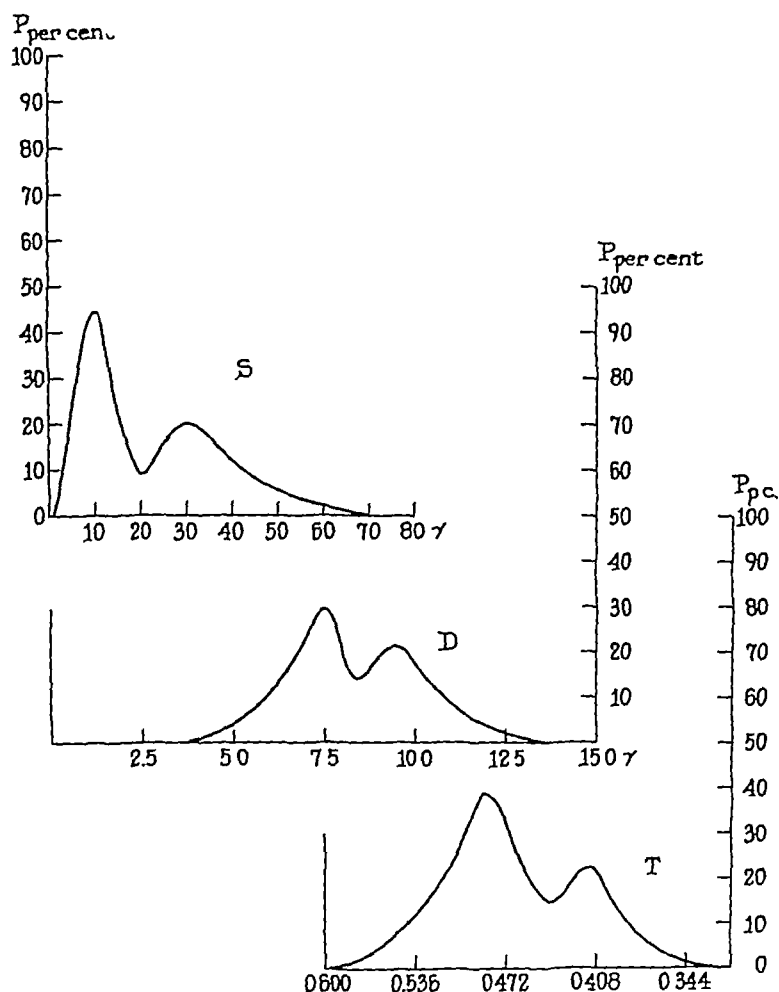

FIG. 4. FREQUENCY DISTRIBUTIONS AND THEIR INTEGRALS FOLLOWING A HEMOLYTIC EPISODE

Ordinates, abscissae, etc., as in fig. 1

lysin, on an abscissa showing the amount of lysin in the system in γ (or the tonicity of the system in tonicity units in the case of hypotonic NaCl)

4. NORMAL VALUES

To explore the range of normal variation, the frequency distributions of resistances to saponin, digitonin, and hypotonic NaCl have been obtained at 25 C for the red cells of 12 normal blood donors. Table 1 shows the average, lowest, and highest values found for various statistics of the curves. The interdecile difference between the lowest and highest deciles, D_1 and D_2 , has been used as a measure of

scatter, and the skewness has been calculated from the deciles D_1 and D_2 and the median M , as

$$\frac{(D_2 - M) - (M - D_1)}{(D_2 - M) + (M - D_1)}$$

by analogy with Bowley's measure of skewness. The three distribution integrals with average values are plotted, together with the distributions obtained from them by differentiation, in figure 2.

The distribution of resistances to saponin is normally negatively skew, with a long tail spreading out towards its upper extreme. The resistance distribution to digitonin is usually positively skew, and its scatter is relatively small. The normal

TABLE 1

	Average	Lowest	Highest
Saponin			
Median	26.5	22.0	28.5
Lower extreme	3.5	3.0	4.5
Upper extreme	85.0	73.0	96.0
Inter-decile diff	52.5	44.0	57.5
Skewness	-0.30	-0.15	-0.41
Digitonin			
Median	9.20	9.05	9.45
Lower extreme	4.70	3.80	5.35
Upper extreme	13.5	12.5	14.9
Inter-decile diff	4.25	4.05	4.50
Skewness	0.29	0.05	0.36
Hypotonicity			
Median	0.448	0.424	0.472
Lower extreme	0.566	0.584	0.552
Upper extreme	0.328	0.360	0.312
Inter-decile diff	0.131	0.103	0.139
Skewness	0.14	-0.06	0.22

distribution of resistances to hypotonic NaCl at pH 7.0 is usually symmetrical, although it may have a small skewness in either direction. None of the observed distributions shows any great individual variation from the average distribution obtained for normal red cells.

5. DISCUSSION, WITH EXAMPLES

The frequency distributions obtained experimentally with each lysin represent the distribution of the resistances of the N cells in the general circulation at the time the blood is drawn. This number is maintained at a constant level in the normal individual by the addition of new cells at a rate P and by the removal of old cells at a rate Q , so that $dN/dt = P - Q$. Changes in the rates of production and destruction result in changes in the value of N accompanied by *transient* changes in the form of

the resistance distribution, variations in the distribution of the resistances of the cell in the population N can, however, be brought about in another way. The P cells which are added to the population N in each unit of time themselves constitute a population with resistances distributed according to some form of frequency distribution, the same applies to the Q cells which are removed from the population N in unit time, and it can be shown that in the steady state the distribution of resistances in the population P is the same as that in the population Q , that the form of these distributions determines the form of the distribution in the population N , and that, if the life of the red cell in the circulation depends on its resistance to the lysis in question, the P and Q distributions must be more negatively skewed than the N distribution.¹⁵ It follows that *persistent* changes in the form of the distribution of resistances in the population N are reflections of persistent changes in the form of the distribution of resistances in the populations P and Q , and that *transient* changes in the distribution of resistances in the population N are due to sudden changes in the rate at which new cells are added to it, or in the form of the resistance distribution in the population P . Sudden changes in the rate of removal of old cells or in the distribution of resistances in the population Q can conceivably produce similar transient changes in the population N .

Hemorrhagic or hemolytic episodes supply the clearest instances of transient changes in the form of the distribution of resistances to saponin, digitonin, and hypotonic NaCl, as is illustrated by the following two examples.

Example 1 Hemorrhage from duodenal ulcer seven days before. Red cells 2.2 millions, Hb 5.7 Gm, reticulocytes 6 per cent. All three resistance distributions bimodal. Saponin distribution has modes at 10 γ and 43 γ , digitonin distribution has modes at 9.5 γ and 12 γ , hypotonic NaCl distribution has modes at 0.520 and 0.360 tonicity units (fig. 3).

Example 2 Hemolytic anemia accompanying metastatic carcinoma with pylorus as the primary site. Red cells, 1.8 millions, Hb 4.6 Gm, reticulocytes 13 per cent. All distributions bimodal. Saponin modes, 10 γ and 30 γ , digitonin modes, 7.5 γ and 9.4 γ , hypotonic NaCl modes, 0.488 and 0.416 tonicity units (fig. 4).

In these cases, the bimodalities are presumably due to a new population with its own frequency distribution of resistances having been added to the existing one at the time of the hemorrhagic or major hemolytic episode. The existing data do not allow the situation to be analyzed further. It would be almost certainly wrong, for example, to identify one of the modes as being produced by the reticulocytes in the population. All that can be said is that *at least* two distinguishable frequency distributions are superimposed.

Illustrations of persistent abnormalities in the form of one or more of the frequency distributions are less striking and not so easy to supply. Apart from the marked change in the distribution to saponin found in pernicious anemia in relapse¹⁶ and to lysolecithin found in congenital hemolytic icterus,⁹ the abnormalities are usually encountered during routine determinations of the resistance distributions in hypoplastic and toxic anemias, and in the anemias associated with leukemia, the various forms of lymphoma, etc. The italicized values found in the following three cases are outside the normal range of variation as given in Table 1.

Example 3 Hodgkin's disease Red cells, 3.9 millions, Hb 10.4 Gm Saponin distribution median 18%, lower extreme, 2%, upper extreme, 100%, skewness, -0.60 Digitonin distribution median, 1%, lower extreme, 3%, upper extreme, 12.5% Hypotonic NaCl distribution median 0.456, lower extreme, 0.636, upper extreme, 0.294, interdecile difference, 0.233

Example 4 Aplastic anemia Red cells, 1.9 million, Hb, 5.2 Gm Saponin distribution median, 2%, lower extreme 4%, upper extreme, 56%, interdecile difference, 40%, skewness, -0.35 Digitonin distribution median, 9.1%, skewness 0.45 Hypotonic NaCl distribution, no abnormalities

Example 5 Normocytic anemia due to chronic infection Red cells, 3.8 millions, Hb, 9.2 Gm Saponin distribution median, 31%, lower extreme, 2%, upper extreme, 63%, skewness, -0.03 Distributions to digitonin and to hypotonic NaCl substantially normal

Much more data will have to be accumulated before it is possible to classify these persistent abnormalities in the form of the frequency distributions to lysins. It is significant that all those which I have observed have been associated with anemia. In the meantime the persistent abnormalities can be looked upon as having much the same significance that abnormal Price-Jones curves would have, i.e., as showing that the normal red cell population has been partially or wholly replaced by populations having different resistance characteristics.

SUMMARY

A method is described for determining quantitatively the form of the resistance distributions of red cell resistances to simple hemolysins. The normal range of variation is given for the resistance distributions to saponin, digitonin, and hypotonic NaCl, all at pH 7.0, and examples of departures from the normal, which may take the form of bimodalities after hemorrhagic or hemolytic episodes or of more persistent changes in the characteristics of the distributions, are provided.

THE HEMOGLOBIN OF HEALTHY COLLEGE UNDERGRADUATES AND COMPARISONS WITH VARIOUS MEDICAL, SOCIAL, PHYSIOLOGIC AND OTHER FACTORS

By CLARK W. HEATH, M.D.

AN UNUSUAL opportunity for obtaining data concerning the blood of healthy young college men has been afforded in the work of the Grant Study and the Harvard Fatigue Laboratory. The subjects were Harvard undergraduates, selected for good health and adjustments.* In addition to medical examination and blood examination, these men were studied by a variety of technics including physiologic tests, anthropologic measurements and psychologic and social surveys. The average age was 19 years, 7 months, the range 17 years to 25 years. Sixty-one per cent were born in Northeastern United States. The remainder were born elsewhere in the United States with the exception of three foreign-born. Table 1 indicates the distribution of hemoglobin findings and red blood cell counts in 153-259 of these young men.

METHODS

Sahli hemoglobin determinations and red blood cell counts were obtained on oxalated venous blood in the course of the physical examination. Sahli tubes and solid glass standard were calibrated from bloods whose oxygen capacity had been ascertained, converting to grams of hemoglobin by the factor 0.746. Oxygen capacities were determined by the Van Slyke method in the Fatigue Laboratory on heparinized arterial blood, taken as a rule in the fasting state. The two determinations were made at varying times apart, usually a few days or weeks.

The means of hemoglobins are only slightly less, as a rule, than those reported elsewhere in this country, but higher than those reported from England.† The wide variation of hemoglobins is worthy of comment. In the total series of Grant Study participants only one case was omitted in which rather low hemoglobin seemed possibly the effect of a chronic infection. In other instances of lower

hemoglobin levels, although determinations were repeated, only the first determination is reported here. Cases in which the hemoglobin level was at the extremes, as 13.5 grams or less, and 16.0 grams or more, gave no clinical evidence to explain such levels. In one young man the initial Sahli hemoglobin was 13.1 Gm, one week later, 13.4 Gm, six weeks after that, 14.35 Gm, finally, four days after the third determination his hemoglobin was 14.6 by the Van Slyke method. Another subject was observed to have a hemoglobin level of 16.1 Gm. Two years previously, determinations at Thorndike Memorial Laboratory were 15.8 Gm and 17.2 Gm, two weeks apart. One month after the Sahli determination at the Grant

Study, the hemoglobin by the Van Slyke method was only 14.6 Gm. With due consideration for the variations that may take place in the hemoglobin level of an individual from day to day, as well as the possible errors in determination,* it appears that individual persons have hemoglobin ranges that are native to them.

* Even under carefully standardized conditions, the errors in performing the Sahli test upon the same blood sample may be considerable. In one series of observations, when the test was repeated by the same observer, only 13 per cent of the readings were identical, 77 per cent were within 2 per cent, or 0.31 Gm, 95 per cent within 3 per cent, or 0.47 Gm. When the test was repeated by different individuals, 19 per cent of the readings were identical, only 32 per cent were within 2 per cent, or 0.31 Gm, only 44 per cent within 3 per cent, or 0.47 Gm. (Figures furnished by G. A. Daland, Thorndike Memorial Laboratory.)

and that are compatible with good function of their particular physiology. It is hardly necessary to detail the wide variation of other measurements in any population, such as height, weight, basal metabolism and pulse rate, variations not necessarily due to health, nutrition or other environmental influences.

An attempt has been made to search for factors which might correlate with higher or lower hemoglobins in these 258 men, selecting from the extensive data available in the Grant Study. As will be seen, the search was largely unavailing. Only in the case of sitting pulse rate taken at the time of medical examination and blood collection was there a statistically significant relationship with hemoglobin level. Other factors showed certain trends as will be indicated.

The method of relating hemoglobin level to various factors is illustrated by table 2. The Chi-square (X^2) test,¹² which compares observed results with those expected by chance, was employed. Table 2 shows that there is an excess of individuals having lower hemoglobins who have slower pulse rates, and a deficiency of individuals with lower hemoglobins having faster pulse rates. (The average

TABLE 2.—Comparison of Hemoglobin and Pulse Rate (Sitting, at time of Medical Examination)

Pulse Rate	Hemoglobin					
	15.1 Gm /100 cc. or less		15.2 Gm /100 cc. or more		Totals	
	No	%	No	%	No	%

Totals	117	100.0	127	100.0	244	100.0

hemoglobin was 15.09 Gm. for those having pulse rates of 75 or less, 15.39 Gm. for those having pulse rates of 76 or more.) The Chi-square test applied to this four-fold table shows that a relationship of this extent could occur by chance less than once in 50 times ($P = .02$). Arbitrarily, this is taken as a significant relationship. Comparison of Sahli hemoglobin with the hemoglobin by the Van Slyke method, with red blood cell count, with hematocrit shows much closer relationship than this, as would be expected. Hemoglobin level compared to each of the various factors that follow, however, never reached the probability of one in 50 ($P = .02$), and rarely one in 20 ($P = .05$).

Pulse rates during the physical examination determined in recumbent and standing positions also showed a tendency for the slower rates to accompany lower hemoglobin, faster rates higher hemoglobin, but not to the extent of sitting pulse rate and not significant by the described criterion. Such tendencies, however, help to confirm the general observation that hemoglobin is often higher in individuals with faster pulse rates. Since the pulse rate is a somewhat sensitive indicator of emotional state, it is likely that the hemoglobin in these men has also reflected to some extent emotional disturbance or excitement toward the examination and the drawing of blood, and although excitement was not a very marked response in these men, it was quite obvious in some cases. Increase of the red blood cells and

hemoglobin in excitement in man and animals has been described, the so-called "emotional polycythemia"¹³ A group of the present subjects who have been judged by the psychiatrist to have greater than average instability of the autonomic

nervous system functions showed a tendency to have higher hemoglobins (as well as higher pulse rates) than those not so judged. On the other hand, no significant relationship was seen between hemoglobin level and a medical estimate of general reaction to stress or of immediate reaction to venipuncture.

The additional comparisons shown in table 3 were made in the attempt to throw further light on the question of the relationships between the blood and pulse rate or emotional excitement.

‡Masculine component compared to Sahli hemoglobin	253
‡Masculine component compared to O ₂ Capacity	152
‡Masculine component compared to hematocrit	252
‡Masculine component compared to red blood cells	254
‡Posture compared to Sahli hemoglobin	213

* Order of birth was divided into (1) only child or first-born, (2) second-born, (3) third-born or later in rank of birth

† Dietary information was obtained from diet history of servings consumed and weighed average servings in the dormitory (See reference 1, page 128)

‡ There was a tendency, not significant, for the more pyknic (i.e. greater fatness and roundness and the less masculine body-builds to have somewhat higher blood levels

None of these comparisons showed a significant relationship according to the Chi-square test. The *tendency* was, however, for faster pulse rates to be associated with higher blood levels, in all instances but the two when recumbent and standing pulse rates were compared to red blood cell count. The consistency of these trends confirms the impression that higher blood levels tend to be found among individuals with faster pulse rates. It is possible, of course, that under the conditions of these observations, a type of emotional response in some individuals may result in lower blood levels with elevated pulse rates. It is worth noting that the trends became less significant as the effect of exercise on the pulse came into evidence. No relationship between work performance and hemoglobin could be established.

Comparisons with blood pressure were made as shown in table 4. Although no significance could be attached to the findings, the trends were consistent enough to suggest the predominance of lower hemoglobin levels in individuals having higher systolic blood pressures, and higher hemoglobin levels in those with higher diastolic pressures.

The comparisons given in table 5 were made in order to explore the possible relationships between socio-economic, dietary, physiologic, medical and body-build factors with blood levels. None of the comparisons showed significant relationships and no conclusions can be drawn other than that the hemoglobin level seems to be independent of these factors in healthy college men.

COMMENT

Such negative findings in a relatively homogeneous group of young men should not be unexpected. They do not necessarily mean that relationships of hemoglobin with various environmental factors such as nutrition and disease incidence would not be present in larger population studies. Certainly, there have been shown to be distinct ranges of hemoglobin at different ages, in the two sexes, and in certain geographic areas where there are different nutritional influences. The relatively large range of hemoglobins in healthy young men remains unexplained by the present study. Emotional factors may be a partial explanation but future study will have to show the relative place of this and other factors.

SUMMARY

1. The distribution of hemoglobins (obtained by the Sahli method on venous blood and by the O_2 capacity method of Van Slyke) and the red blood cell counts of 153 to 259 college men, selected for participation in the Grant Study, are reported.

2. There is a statistically significant relationship between the hemoglobin and the pulse rate (those subjects having higher pulse rates tending to have higher hemoglobins). This relationship is apparently associated with emotional factors.

3. No significant relationship could be established between hemoglobin level and a variety of other factors, including socio-economic, dietary, physiologic, medical, body-build and others.

STUDIES OF THE STAPHYLOCOAGULASE REACTION NATURE AND PROPERTIES OF A PLASMA ACTIVATOR AND INHIBITOR

By MELVIN H. KAPLAN, P. S., AND WESLEY W. SPINK, M. D.

SINCE Loeb's¹ observation in 1903 that certain strains of staphylococci possessed the property of clotting oxalated plasma, considerable study has been devoted to the mechanism of the staphylocoagulase reaction and to its possible role in staphylococcal infections. The ability to clot oxalated plasma has been found to be a property generally associated with pathogenic strains of staphylococci, however, the relationship between clotting activity and pathogenicity has not been clearly understood. Studies of the mechanism of the clotting action of staphylocoagulase have yielded several conflicting hypotheses.

Gengou² and Vanbreuseghem³ noted that the clots produced from plasma by staphylococci underwent dissolution. Purified fibrinogen preparations were not clotted but underwent lysis without clot formation. In view of these observations, both authors agreed that the coagulant activity of staphylococci could be attributed to a fibrinolysin, whose action resulted in clotting only in the presence of a suitable plasma inhibitor. Gratia⁴ proposed the term coagulase for the clotting agent elaborated by staphylococci and reported that the participation of proserozyne (prothrombin) or cytozyme (thromboplastin) was not necessary for the action of coagulase, plasma freed of these substances by adsorption methods remained clottable. He also noted that purified fibrinogen could not be clotted by staphylococci, but clotting occurred readily when a small amount of a plasma preparation was added, which had been freed of its content of fibrinogen, proserozyne, and cytozyme. Gratia concluded that the clotting activity of staphylococci was due to the elaboration of coagulase, but for the elaboration of this agent a nutrient factor was required which was not present in purified fibrinogen preparations, but was present in plasma. However, in opposition to these reports, Cruickshank⁵ and Walston⁶ both reported that coagulase acted on fibrinogen directly, and was therefore similar in its action to thrombin. In the most recent studies, Smith and Hale⁷ confirmed the earlier reports and showed that fibrinogen was not clotted by cell-free coagulase unless there were added small amounts of human or rabbit plasma, serum, or testicular extract. The accessory clotting factor present in the plasma and testicular extract was not identical with either prothrombin or thrombokinase. The authors proposed that the function of this factor was to convert staphylocoagulase into an active thrombin-like substance and they therefore termed it activator. It was also suggested that the relative insusceptibility of the plasmas of certain animal species to the clotting action of coagulase could be attributed to a deficiency of activator in these plasmas.

From the Department of Internal Medicine, University of Minnesota Hospitals and Medical School, Minneapolis.

Aided by a grant from Sharp and Dohme, Inc.

Dr. Robert Pennell and Dr. W. F. Verwey of the Medical Research Division, Sharp and Dohme, prepared and supplied several preparations used in these studies.

The occurrence in the serum of a factor which participated in the coagulase reaction was also observed in this laboratory, confirming the report of Smith and Hale.⁷ This factor has been extracted from human plasma, and its nature and properties examined in an attempt to elucidate further its role in the clotting mechanism. In addition, it has also been observed that an inhibitor for coagulase could be obtained from normal human plasma and from the plasma of certain species of animals. This inhibitor appeared to play a significant role in determining the susceptibility of these plasmas to the action of coagulase. In the present report, the properties and action of the activator and inhibitor for coagulase are described.

MATERIALS AND METHODS

1 *Staphylocoagulase* The source of coagulase throughout this study were viable cultures of coagulase positive strains of staphylococci which had been grown in tryptose-phosphate broth for 48 hours.

2 *Fibrinogen* The fibrinogen preparation* employed was a dried product which had been precipitated repeatedly from pooled normal human plasma by the method of alcoholic fractionation.⁸ A 2 per cent solution of the dried powder was used.

3 *Thrombin* The preparation was a 1:10 dilution of a commercial product derived from rabbit blood.[†]

4 *Plasma defibrinated by heating* Oxalated or citrated plasma was heated to 56°C, kept at this temperature for three minutes, and then immediately cooled in running water. The flocculated fibrinogen was removed by centrifuging. The defibrinated plasma thus obtained possessed no thrombic activity for fibrinogen.

5 *Plasma coagulase test* Two tenths ml. of a forty-eight hour culture of a given strain of staphylococcus was added to 0.5 ml. of citrated or oxalated plasma, and the tube placed in a water bath at temperature 37°C. Periodic observations were made to note the time and degree of clotting. A test was considered positive only if a cohesive clot was formed within twenty-four hours, while a test was considered negative if no clot was formed after incubation for twenty-four hours.

EXPERIMENTAL

I PARTICIPATION OF A PLASMA FACTOR IN THE STAPHYLOCOAGULASE REACTION

Fresh human plasma has been generally employed as a substrate for use in the routine staphylocoagulase test. Because of the availability, however, of such products as frozen plasma, dried plasma, and dried fibrinogen, it was of interest to determine whether these materials could be substituted for fresh plasma in the test. Accordingly, a series of pathogenic strains of staphylococci were tested with these substrates as well as with fresh human plasma. Using fifteen different strains as a source of coagulase, it was found that the substitute substrates were much less susceptible to coagulation than the fresh plasma. As shown in table 1, of the fifteen strains which were coagulase-positive when tested with fresh human plasma, only seven clotted plasma which had been rethawed from the frozen state, three clotted reconstituted dried plasma, and none clotted solutions of lyophilized fibrinogen even after incubating for a period of twenty-four hours. Moreover, in those instances in which clotting of the frozen or dried samples of plasma occurred, the clotting time was prolonged, ranging from twelve to twenty-four hours as contrasted with one to two hours for samples of fresh plasma. The relative refractoriness of these three substrates to clotting by coagulase could not be attributed to a deficiency of clottable fibrinogen since all three substrates were readily clotted by such agents as thrombin, snake venom, and papain within two to eight minutes.

* The fibrinogen preparation was kindly supplied by Sharp and Dohme, Inc.

† Hemostatic Globulin, Lederle Laboratories, Inc.

A possible explanation for the apparent resistance of these samples of fibrinogen and plasma to clotting was that they were deficient in some clotting factor present in fresh plasma. Prothrombin was excluded as this factor since the Quick⁹ prothrombin levels of both the frozen and dried plasma were practically the same as that of fresh plasma, 1 e, 12.8, 12.3, and 12.5 seconds respectively. Tests for an accessory clotting factor were therefore carried out with fresh human serum. As a test substrate, 0.2 ml of fresh human serum was mixed with 0.5 ml of fibrinogen, and susceptibility to clotting determined by addition of 0.2 ml of a staphylococcus culture. It was at once apparent that the addition of serum rendered the fibrinogen readily clottable by coagulase. Further, the clotting which resulted was not due to the presence of thrombin in the serum, since interference by thrombin could be excluded by suitable dilution of the serum or by destroying its thrombic activity.

* This plasma was stored in the frozen state for two years before thawing

by heating at 60 C for thirty minutes. These procedures still permitted the activity of the accessory coagulase factor to be readily demonstrated.

The most satisfactory source of this accessory factor was plasma from which the fibrinogen was removed either by heating to 56 C for three minutes, or by precipitation at one-fourth saturation with ammonium sulfate. These preparations had the advantage that they possessed no thrombic activity. As shown in table 2, when 0.2 ml of such a defibrinated sample of plasma was added to fibrinogen, clotting occurred almost as readily as with the fresh plasma. Fibrinogen to which no defibrinated plasma had been added was not clotted by any of these strains. This failure to clot could not be attributed simply to the destruction of the fibrinogen by the fibrinolytic action of the staphylococci, as had been suggested by Gengou.² Indeed, of the five strains included in table 2, only two were found to

have destroyed the fibrinogen at the end of twenty-four hours as was indicated by the fact that the addition of thrombin did not result in a clot. The other three strains apparently exerted no appreciable fibrinolytic effect in the twenty-four hour period, since fibrin clots were obtained following the addition of thrombin. Similar results have been obtained with a larger series of tests and it was therefore concluded that the failure of preparations of fibrinogen to be clotted by coagulase was not due to the action of a fibrinolysin but rather to the deficiency of an accessory clotting factor.

This clotting factor, as it has been previously pointed out, has been termed an activator of coagulase by Smith and Hale.⁷ In the present state of knowledge,

such a function should be regarded as highly hypothetical, however, for purposes of uniformity the term activator has been retained in the present report.

2. TESTS OF PLASMA FRACTIONS FOR ACTIVATOR CONTENT

In order to determine which of the plasma protein fractions contained the activator, human citrated plasma was fractionated into five components at increasing saturation with ammonium sulfate, and each fraction then tested for its content of activator. Precipitates were obtained at 25, 40, 60, 80, and 100 per cent saturation with ammonium sulfate. Each precipitate was washed once in the appropriate concentration of ammonium sulfate, and redissolved in distilled water to a volume one-half that of the original plasma. The solutions were then dialyzed against physiological saline solution in the cold for eighteen to twenty-four hours.

The method of titration for activator was as follows. Serial dilutions with physiological saline solution were made with each fraction in 0.5 ml. volumes. To each dilution was added 0.5 ml. of a forty

eight hour broth culture of a standard strain of staphylococcus (Bur), and incubation carried out for one hour in a water bath at 37 C To each tube was added 0.5 ml of fibrinogen solution, the tubes shaken, and incubation carried out for four hours The titer of activator in the sample was taken as the highest dilution which yielded a solid cohesive matrix clot

As shown in table 3, the activator was concentrated essentially in the fraction obtained between 80 and 100 per cent saturation, while the fraction between 60 and 80 per cent saturation possessed smaller amounts of activity Activator thus appeared to be associated with the crude albumin fraction of the plasma

A more precise characterization of the nature of activator was made possible by testing human plasma fractions prepared by alcoholic fractionation * It has been shown by Cohn and collaborators⁸ that the plasma proteins may be separated into five fractions on the basis of their differential solubility in ethanol-water mixtures at low temperatures and at varying pH and ionic strength These five fractions, I, II + III, IV-1, IV-4, and V, as well as a sample of crystalline serum albumin, were

TABLE 3—Activator titer of human plasma fractions prepared by ammonium sulfate precipitation

1	25% sat $(\text{NH}_4)_2\text{SO}_4$	0
2	25-40% $(\text{NH}_4)_2\text{SO}_4$	0
3	40-60% $(\text{NH}_4)_2\text{SO}_4$	0
4	60-80% $(\text{NH}_4)_2\text{SO}_4$	4
5	80-100% $(\text{NH}_4)_2\text{SO}_4$	16

* Highest dilution of the test substance which when mixed with fibrinogen permitted clotting by coagulase in four hours

titrated for their relative content of activator The solutions in each case were made up to contain 200 mg of the dried fraction in 100 ml of 0.1 M phosphate buffered saline, pH 7.4

As shown in table 4, activator was found to a significant extent only in fractions IV-4 and V The greater amount of activity appeared in fraction IV-4, which is made up chiefly of alpha and beta globulins Fraction V, which is essentially albumin, contained a somewhat smaller amount of activator, while crystalline albumin was without activity

From the above findings, it appeared that activator is probably not an albumin although it is precipitated with this protein fraction by ammonium sulfate In plasma fractions obtained by alcoholic fractionation, activator appeared to be associated with the alpha and beta globulins

3 PREPARATION OF DRIED ACTIVATOR MATERIAL FROM CITRATED HUMAN PLASMA

The activator preparations used in the subsequent studies were prepared from the fraction of plasma precipitated between 60 and 100 per cent saturation with

* These fractions were supplied by Dr E J Cohn and his associates The materials were made possible through contracts between Harvard University and the Office of Scientific Research and Development and the plasma was obtained through the American Red Cross and more recently through the Massachusetts Civilian Blood Donor Program

ammonium sulfate To 1 volume of fresh citrated human plasma was added slowly with continuous stirring 1.5 volumes of saturated ammonium sulfate, and the mixture allowed to stand for four hours at temperature 4 C This precipitate obtained at 60 per cent saturation was removed by filtration in the cold and discarded To the supernate, solid ammonium sulfate was added to saturation, and the mixture was usually allowed to stand overnight in the refrigerator before filtering The fraction thus obtained between 60 and 100 per cent saturation was dissolved in a small amount of distilled water and dialyzed against physiological saline solution for eighteen hours in the cold The resulting solution was then dried from the frozen state by the lyophile process and the resulting light yellow powder used

without further purification It was found to be completely stable for at least a month when stored in the cold Solutions of activator employed in the present study were usually made up in a concentration of 200 mg of dried preparation per 10 ml of distilled water

4 PROPERTIES OF ACTIVATOR

A *Thermolability* Smith and Hale⁷ found the activator present in rabbit testicular extracts to be completely inactivated after heating at 56 C for thirty minutes Such thermolability, however, has not been observed with activator derived from human plasma Heat sensitivity tests, using both defibrinated plasma and am-

monium sulfate fractions as a source of this material, have indicated no apparent inactivation following exposure to 56 C for thirty minutes. Indeed, as shown in table 5, complete inactivation of defibrinated plasma did not occur even after heating at 100 C for thirty minutes, although there was some loss of activity. Strong boiling for thirty minutes caused complete destruction.

B Stability at various pH Solutions of activator were markedly stable within a wide range of acid and alkaline pH. The effect of pH variation was determined by mixing given amounts of activator with a series of buffers from pH 2.0 to 10.0 and then permitting these mixtures to stand for four hours at room temperature before neutralizing. The mixtures thus treated showed no measurable loss of activator titer.

C Inactivation by pepsin and nitrous acid Since activator was stable at acid pH, it was possible to determine whether it could be destroyed by the proteolytic action of pepsin. Accordingly, 1.0 ml of activator solution was adjusted to pH 3.0, and incubated with 1.0 ml of a 0.05 per cent solution of pepsin (Merck) for

TABLE 6 —*The inactivation of activator by treatment with (1) pepsin and (2) nitrous acid*

Expt No	Reaction Mixture	Activator Titer
1	(a) Activator + pepsin	0
	(b) Activator + saline control	8
2	(a) Activator + nitrous acid	0
	(b) Activator + saline control	4

thirty minutes at 37 C. At the end of this period, pepsin action was stopped by neutralizing the mixture with $\frac{1}{2}$ M phosphate buffer, pH 7.5. The resulting mixture was then titrated for its activator content. As shown in table 6, activity of activator was completely lost by this treatment, while control samples, in which saline solution was substituted for pepsin and which were subjected to the same temperature and pH, remained fully active.

Treatment of activator solutions with nitrous acid also resulted in rapid inactivation. On addition of dilute sodium nitrite solution to activator preparation at pH 3.0, complete inactivation was observed within fifteen minutes (table 6). Since the action of nitrous acid within this period is primarily directed against alpha-amino groups, it would appear that the action of activator is dependent upon the integrity of alpha-amino groups in the molecule.

The data obtained would indicate that activator is a relatively stable protein constituent of the plasma. It is precipitated between 60 and 100 per cent saturation with sulfate, but in alcoholic fractions it is associated more closely with the alpha and beta globulins. It is nondialyzable, is not readily destroyed by heating below 100 C, and is entirely stable between pH 2.0 to 10.0. Its activity is completely destroyed by nitrous acid or by the proteolytic action of pepsin.

5 PRESENCE IN NORMAL HUMAN PLASMA OF A SUBSTANCE INHIBITING THE COAGULASE REACTION

It was noted that when some samples of human defibrinated plasma were employed as a source of activator, clot formation occurred much more rapidly when the samples were diluted. This same accelerating effect was observed also on diluting some activator preparations. One given activator preparation, for example, when mixed with fibrinogen and coagulase, permitted clotting to occur in eight hours, but when this same preparation was diluted 16-fold, clotting occurred in two hours. This observation suggested the presence in these activator preparations of an inhibitor which interfered with clot formation, and that the action of the inhibitor could be suppressed by suitable dilution*. It was noted, however, that the inhibitory effect did not occur with all preparations of activator.

On fractionation of human oxalated plasma by means of ammonium sulfate, the inhibitor was found to be present in the globulin fraction obtained at half-saturation. The inhibitory action of such a globulin preparation is demonstrated in the following experiment. One-tenth ml of a 4 times concentrated human globulin preparation was added to a mixture containing 0.5 ml of activator solution, 0.5 ml of coagulase and 0.5 ml of fibrinogen, and the clotting time noted. The result

TABLE 7 — *Inhibitory effect of a plasma globulin factor on the coagulase reaction*

Globulin	Activator	Coagulase	Saline	Clotting Time
ml	ml	ml	ml	hrs
0.1	0.5	0.5	0	> 24
0	0.5	0.5	0.1	2

was compared with a control test, in which 0.1 ml of saline solution was substituted for the 0.1 ml of test preparation. As shown in table 7, the mixture containing the plasma globulin preparation was not clotted even after twenty-four hours, while a clot appeared in the control tube in two hours. The coagulase reaction was thus entirely inhibited by the globulin preparation.

In order to compare quantitatively the content of inhibitor in different plasma fractions, a method was devised for determining inhibitory titer. The inhibitory titer of a given sample was measured as follows. Serial dilutions of the test sample were made in saline solution in 0.5 ml volumes. To each tube, 0.5 ml of activator solution and 0.3 ml of coagulase was added, and these mixtures were then incubated for sixty minutes. Finally, 0.5 ml of fibrinogen was added, and the tubes incubated for four hours. The highest dilution of the test sample preventing clotting completely at the end of this four hour period was taken as the inhibitory titer.

Table 8 demonstrates that practically all of the inhibitor present in human plasma is associated with the fraction obtained at 25 to 40 per cent saturation with ammonium sulfate. When such globulin preparations were dialyzed against dis-

* The greater susceptibility to clotting of plasma which is diluted also led Lominski and Roberts to the recognition of an inhibitor in the plasma which they have independently described.¹⁰

tilled water, the inhibitor was found to be associated with the insoluble euglobulin fraction, while the pseudoglobulin fraction contained little or no inhibitory action

It appeared possible that the presence of this globulin inhibitor in high concentration might be in part responsible for the resistance to the action of coagulase observed in some human plasmas,⁶ and in the plasmas of certain species, such as the guinea pig,³ mouse, and fowl.⁷ Smith and Hale⁷ stated that the resistance of these plasmas might be explained by their deficiency of activator. The participation of an inhibitor was not recognized.

In order to determine the relationship of the inhibitor to coagulase susceptibility, tests were carried out for the presence of inhibitor in both susceptible and resistant plasmas. Human and rabbit blood was used as a source of susceptible plasma, while the resistant plasma was obtained from the guinea pig. Previous studies have indicated that, of these three species, rabbit plasma is the most susceptible.¹¹ Guinea pig plasma is unusual in that it is not clotted at 37 C, but is clotted slowly at 25 C.^{3, 7}

TABLE 8—*Titer of inhibitor in human plasma fractions*

	Plasma Fraction Tested	Dilution of Fraction					
		1	2	4	8	16	32
1	25-60% sat (NH ₄) ₂ SO ₄	o	o	o	o	+	+
2	25-40% sat (NH ₄) ₂ SO ₄	o	o	o	o	+	+
3	40-60% sat (NH ₄) ₂ SO ₄	+	+	+	+	+	+
4	60-100% sat (NH ₄) ₂ SO ₄	+	+	+	+	+	+
5	Pseudoglobulin	+	+	+	+	+	+
6	Euglobulin	o	o	o	o	+	+

+ = clot formed, o = no clot formed

The susceptibility of each plasma was tested by the routine coagulase test both at 37 C and at 20 C. It was found that at 37 C the clotting of human and rabbit plasmas occurred in thirty minutes, while clotting of guinea pig plasma occurred in sixty minutes. At 20 C, the human and rabbit plasmas were clotted in two hours, while guinea pig plasma was clotted in eight hours.

Thus, in this study, the effect of temperature was precisely the reverse of that previously reported. Guinea pig plasma was definitely clotted by the strain of staphylococcus employed, and the clotting occurred more rapidly at 37 C. However, this plasma was still less susceptible than the plasmas of the other two species.

The inhibitor content of each plasma was determined by testing the extracted globulin fraction, since it was desired to avoid any possible interference resulting from the presence of activator in the whole plasma. Each sample was first defibrinated at 56 C, and the globulin precipitate then separated from the resulting sample by half-saturation with ammonium sulfate. The precipitate was removed by filtration and was dissolved in distilled water, and the volume brought up to that of the plasma originally used. Each preparation was then titered for its inhibitor content.

As shown in table 9, the rabbit preparation contained no inhibitor by the method employed, while both the human and guinea pig globulin preparations possessed a titer of 8. The absence of inhibitor in the rabbit was interesting in view of the marked susceptibility of the plasma of this species, however, an inverse relationship between inhibitor level and susceptibility did not seem to be general as was indicated by the similar levels of inhibitor in human and guinea pig plasmas.

Since susceptibility must depend also on the presence of activator in the plasmas, the plasma of each of these three species was next analyzed for their content of activator. Titrations were performed both on defibrinated samples and on the albumin fractions separated between 60 and 100 per cent saturation. Each albumin precipitate was dissolved in distilled water and brought up to the original plasma volume, so that the concentration of activator was presumably the same as that in the plasma.

As shown in table 9, the activator titer of the guinea pig plasma was significantly lower than either the human or rabbit plasma. Thus, the relative titers of activator and inhibitor in the plasmas of these species appeared to explain their degree of susceptibility to the action of coagulase. Rabbit plasma which was most susceptible

TABLE 9—*The levels of inhibitor and activator in human, rabbit, and guinea pig plasmas*

Plasma of Species Tested	Inhibitor Titer of Globulin Fraction	Activator Titer of Defibrinated Plasma	Activator Titer of Albumin Fraction
Human	8	8	8
Rabbit	0	16	8
Guinea Pig	8	4	2

contained a high level of activator and no inhibitor, while guinea pig plasma which was less susceptible than that of the rabbit contained less activator and a more elevated level of inhibitor. The susceptibility of the human plasma, which also contained an elevated level of inhibitor may perhaps be explained by the high level of activator which it possessed.

The action of the inhibitor did not seem to be specifically exerted on activator. This conclusion followed from the repeated observations that plasma samples could be readily separated into inhibitor-containing and activator-containing fractions, the activities of which were entirely independent of each other. Further, as shown in table 9, the separation of activator from defibrinated plasma did not result in an increase in the titer of activator, as might be expected, if activator were freed from an inhibitor. The evidence, therefore, suggests that the inhibitor does not combine with activator, but acts on some other factor in the coagulase reaction, presumably coagulase.

DISCUSSION

The present report has confirmed previous observations in that the coagulase reaction involves the participation of a plasma factor which has heretofore not been described. Dried plasma and plasma stored in the frozen state for long periods

are not readily clotted by coagulase since they contain reduced amounts of this reactive factor. The present studies have demonstrated that this plasma factor is a protein which is precipitated with the crude albumin fraction by means of ammonium sulfate, but it appears to be more closely associated with the alpha and beta globulins in alcoholic fractions.

Smith and Hale⁷ have proposed that the clotting factor in plasma and testicular extracts is an activator of coagulase. The reaction is held analogous to the activation of thrombin by thrombokinase plus calcium ions. In this regard, the present observation that activator is a protein of considerable stability is not inconsistent with the possibility that it possesses an activating function analogous in some respects to thrombokinase.⁹ However, it is equally probable that activator is the substrate, and that coagulase is the activator. Indeed, it is also entirely possible that no activation occurs but that an interaction of a different nature between coagulase, plasma factor, and fibrinogen is involved which is responsible for the precipitation of fibrin. A study of the chemical kinetics of the reaction is highly desirable, but must await the purification and concentration of these three reactants.

In the course of these studies, it was noted that a globulin could be separated from human plasma which inhibited the staphylocoagulase reaction. The inhibitor was also found in the normal plasma of the guinea pig but was absent in rabbit plasma. Previous studies^{6, 12, 13} have reported that some human plasmas appear to be resistant to the action of coagulase, and have suggested that such resistance may be attributed to the presence of a specific antibody to coagulase. The recent report of Lominski and Roberts¹⁰ has also favored the antibody hypothesis. These authors observed that the inhibitor was a globulin, that it was heat-stable, and that it combined specifically with coagulase. They concluded that these findings could only be consistent with an antibody hypothesis. In opposition to this hypothesis, however, are the reports^{6, 7} that attempts to immunize animals with coagulase or to demonstrate in man the development of resistance to coagulase following staphylococcal infection^{5, 13} have met with failure. It is, of course, possible that the failure to demonstrate the development of resistance in these cases was due to the inadequate methods employed for measuring the inhibitor as Lominski and Roberts¹⁰ suggest. If, then, it be assumed that the antibody hypothesis is correct, the present observations that the inhibitor is present in the plasma of normal guinea pigs, and entirely absent in the normal plasma of the rabbit may be explained only by the assumption that the guinea pig acquires the antibody as a result of a natural or silent immunization, while the rabbit is immunologically insensitive. More exact immunologic studies are required to answer this problem.

The presence of the inhibitor in the plasma of the guinea pig, which has been found resistant to coagulase, and its absence in rabbit plasma which is highly susceptible, suggests that this factor may play an important role in determining species susceptibility. Smith and Hale⁷ have reported that the resistance observed with different species may be attributed to a deficiency of activator. However, it is probable that both activator and inhibitor are the variables which determine

susceptibility. It should be noted, that since the inhibitor apparently combine with coagulase and not with activator, an excess amount of coagulase would produce clotting even in the presence of inhibitor, provided some activator were present. The staphylocoagulase test is then dependent on the quantitative interrelationships of the three variables—coagulase, activator, and inhibitor. The variation in susceptibility which is observed when plasmas of various species are tested with different strains of staphylococci may be a quantitative phenomenon which is dependent upon the relative amounts of coagulase, activator, and inhibitor participating in these clotting systems.

CONCLUSIONS

Dried human plasma and human plasma which has been stored in the frozen state for long periods are not readily clotted by coagulase. Fibrinogen which is sufficiently purified is entirely insusceptible to clotting by coagulase. However, all three substrates—dried human plasma, frozen plasma, and dried human fibrinogen—are readily clotted by coagulase on admixture of a plasma factor.

This accessory substance, referred to as activator, is precipitated from normal human plasma at 60 to 100 per cent saturation with ammonium sulfate. However, it is not present in purified serum albumin preparations, but does occur in alcoholic fractions which largely contain alpha and beta globulins. Activator is a comparatively stable protein which resists heating at temperatures below 100 C, but is destroyed by pepsin or nitrous acid.

A substance inhibiting the coagulase reaction was found present in many samples of normal human plasma. It was associated with the globulin fraction. It was also present in the normal plasma of the guinea pig but was deficient in rabbit plasma. The inhibitor substance acts independently of activator and is therefore believed to inhibit the clotting reaction by its action on coagulase. Either the presence of this inhibitor or a deficiency of activator may be responsible for the failure of coagulase to clot the plasmas of some individuals and of certain animal species.

SOME HEMATOLOGIC EFFECTS OF IRRADIATION*

By WILLIAM BLOOM, M D , AND LEON O JACOBSON, M D

DURING our study of the cellular changes in mammals exposed to external and internal sources of ionizing radiations, evidence was sought for correctness of the idea that small doses of radiations stimulate cellular activity and multiplication. Although this idea is held by a number of radiologists, little basis for it is found in the radiologic literature other than misunderstanding and misquotation of a few important papers. Some of our experiments offered unusual opportunities for a consideration of the question of stimulation. Thus, in those experiments in which there were progressive decreases in the amount of irradiation and in the reactions to focalized irradiation, one could expect to find evidence of stimulating effects if they actually occurred. But our findings in the organs and peripheral blood have been so consistently at variance with the idea of stimulation by small amounts of ionizing radiation that it seems desirable to summarize these observations.

Some of the confusion on this question undoubtedly originates from a loose use of the word stimulation. In the following discussion we shall discriminate between a primary stimulation which results directly in cellular hyperplasia, hypertrophy, or hyperactivity after irradiation, without a stage of obvious previous injury, and a secondary stimulation which might be considered as a reparative process resulting from the necrotizing action of radiation.

MATERIAL AND METHODS

The radiations which were employed in these studies on animals and man fall essentially into two main categories: (1) Externally originating total body irradiation from x, γ rays, fast and slow neutrons; (2) Focal irradiation by externally originating B rays and radioactive isotopes administered enterally or parenterally.

1. *Total body irradiation* The organs of large numbers of rabbits, rats, and mice and those from a smaller number of guinea pigs were obtained for histologic study when the animals were sacrificed at intervals after varying dosages of x and γ rays, fast and slow neutrons. The general plan of these experiments was to start with the LD 50/30 days dose of each agent and to decrease it until no histologic or hematologic changes were observed. In most of the series the total amount of irradiation was given at one exposure, although there were several large and important series in which small amounts of radiation were given repeatedly.

We found it necessary to carry out these experiments for histologic purposes by killing the animals at planned intervals because cytologic examinations of animals

From the Departments of Anatomy and Medicine and the Institute of Radiobiology and Biophysics, University of Chicago.

* Most of the work reported here was done in the histologic and hematologic groups of the Metalurgical Laboratory of the University of Chicago and the Argonne National Laboratory, Chicago, under contract of the Manhattan District No. W-31-109-eng-38. The detailed papers which include references on which this communication is based will be found in the *National Nuclear Energy Series*.

which were found dead were worthless. The series was supplemented with the study of a number of moribund animals.

2. *Focal irradiation* This occurred in the spleens and testes of a few mice given large amounts of irradiation by B rays from an external source of P^{32} . However, the great mass of our experiments with focalized irradiation effects occurred after the intravenous or intraperitoneal injection of radioactive isotopes. In a few series these materials were given intramuscularly or by inhalation. Among the elements studied were the α (Alpha) emitters Ra and Pu, the β emitters P^{32} , Sr^{89} , Y^{91} , and the β and γ (Gamma) emitters Zr^{40} , Ba^{140} , La^{140} , Na^{24} , and the degradation products of Ra. These isotopes were given in dosages starting with the LD 50/30 days and in diminishing fractions thereof.

The tissues were routinely fixed in Zenker-formol, imbedded in nitrocellulose and stained with hematoxylin-eosin-azure II, except for those portions of the tissues which were fixed in alcohol so that auto-radiographs could be prepared.

Whenever possible, studies of the peripheral blood were conducted on the same series of animals in which sacrifices were being made for cytologic study. Where this was not possible, groups of animals were studied in parallel series, in still other experiments, blood counts were made on the animal at the time of sacrifice in an attempt to correlate the peripheral hematologic picture with effects on the blood forming organs. Sampling of peripheral blood was done at intervals varying with the chronicity of the experiment. In all cases, the technics employed were standard hematologic procedures.

From the standpoint of the hematologic studies, the experiments of most significance were (1) those in which an acute single dose of penetrating total body radiation was given (x-rays or fast neutrons) and (2) the experiments in which rats, guinea pigs, mice, and rabbits were exposed chronically to γ rays or x-rays. In one of the chronic gamma ray exposure experiments, the radiation was given daily over an eight hour period, and in another set of experiments, the γ radiation was given twenty-four hours per day. In the chronic x-ray experiments, the daily exposure was given within a few minutes. The daily exposure of these animals, whether exposed to gamma rays or x-rays, extended over long periods up to four years.

OBSERVATIONS

I. CHANGES AFTER A WIDE RANGE OF DOSES OF TOTAL BODY IRRADIATION FROM EXTERNAL SOURCES

One of the effects of total body external irradiation in doses not higher than the LD 50/30 days is to separate those organs which are sensitive to this amount of irradiation and those which are not. In the laboratory mammals which were studied with this dosage, the radiosensitive organs are the gonads, bone marrow, spleen, lymph nodes, thymus, parts of the gastrointestinal tract, skin and bone. Nerve, muscle, and most exocrine and endocrine glands are resistant.¹

It was found that all of the external ionizing radiations in equivalent doses produced similar effects.¹ If the animals had been given the LD 50/30 days dose of x-rays, or γ rays, or fast or slow neutrons, the changes which resulted could not be

distinguished from one another. That is, in examining sections of the organs of these animals, we could not tell which ionizing radiation had been used. With this amount of irradiation the very first changes observed, usually within the first hour, were degenerative changes and death of cells in the blood forming organs, bases of the intestinal crypts and foveolae of the stomach, spermatogonia, and ovarian follicular epithelium or developing ova, and early mild inflammation (mainly edema) of skin.

Mitoses were usually gone by the second hour. There was no evidence of an increase in mitosis. In rabbit bone marrow after 100r of total body x-irradiation, mitoses began to be present again after three hours. They continued through the fourteen hour interval at a level slightly above that seen in controls. At the eight hour stage some of the mitoses were abnormal. During the next hours, the debris increased in amount and was gradually phagocytized. With an LD 50 dose after a few days the blood forming organs became markedly reduced in size and the bone marrow and lymph nodes became aplastic—often completely so.

In the course of one to two weeks the blood forming organs gradually became actively hematopoietic again. Only rarely did this process reach or exceed normal in the bone marrow. Several months usually elapsed before the lymph nodes, thymus, and spleen returned completely to normal.

With progressively smaller doses the degenerative effects were less marked. They became minimal at 50r of x-rays and were just detectable in our animals at 25r of x-irradiation or the equivalent fraction of the LD 50/30 days dose of neutrons. With doses lower than 25r, no changes were found, in animals so treated there was no evidence whatever for either an injurious or stimulating effect.

In the regeneration after external irradiation the only instances of overcompensation of tissue was in bone marrow of rabbits which survived the LD 50/30 days. In them the marrow seemed hyperplastic (both erythropoietic and myelopoietic within two months after exposure).

After the administration of single doses of either x-rays or fast neutrons to rabbits, mice, and rats, an increase in circulating heterophil-leukocytes occurred within the first twenty-four hours with doses up to and beyond LD 50/30 days. In fact, with doses of 500 and 800r in the rabbit Jacobson et al.² noted that two definite statistically significant peaks occurred at circa twelve and twenty-four hours. After doses of this magnitude, a leukopenia invariably followed the heterophil leukocytosis. With doses of 300r and below, only a modest elevation in the number of circulating heterophils occurred and this at about twelve hours. Control animals handled in a comparable manner (except for the actual exposure to irradiation) also had this latter modest peak increase after about twelve hours. Heterophils are the only circulating cells which are initially increased in number after acute total body radiation. Lymphocytes, monocytes, eosinophils, reticulocytes, and platelets are reduced.

As recovery occurs in the hematopoietic organs, however, a "compensatory increase" above normal control values was not uncommonly encountered, particularly for the heterophils and reticulocytes. No significant absolute lymphocyte increase on a compensatory basis was encountered in experiments in which doses

of 800r to 5r acute total body X radiation were administered. In fact, lymphocyte values in the peripheral blood of the rabbit are reduced over a period of ninety days after an acute exposure to 800r. This is in agreement with the slow return of the lymph nodes to normal after irradiation.

After acute doses of x-rays, or fast neutrons Jacobson et al.^{2,3} observed an "abortive rise" in lymphocytes, heterophils, and reticulocytes in rabbits between the fourth and twelfth day after irradiation. This rise may possibly represent an abnormal stimulation in the sense that certain precursors are sufficiently altered to produce a limited succession of abnormal progeny.

Chronic Radiation Experiments

Chronic exposure of groups of rabbits, mice, and guinea pigs to γ rays in daily doses of 0.11, 1.1, 2.2, 4.4, 8.8 γ for eight hours per day or twenty-four hours per day over periods extending beyond three years carried out by Lorenz et al.⁴ has not shown evidence of a stimulating effect on the blood forming tissue which was reflected in the hematologic constituents of the peripheral blood. Similar experiments were conducted with chronic daily exposure of rats to x-radiation, but different in that the daily exposures required only a few minutes.⁵ No evidence of "stimulation" was apparent in the peripheral blood of these animals. In those instances in which an effect occurred, it was invariably a reduction in the number of circulating cells.

No deliberate or well controlled human experiments have been done which are comparable in chronicity to these animal experiments. The experiments of Low-Beer and Stone,⁶ and Nickson, Cantril, and Jacobson,⁷ however, in which human subjects were exposed up to a total dose of 300r total body given in divided doses of from 5 to 20r (x-ray) produced a general reduction in the various hematologic constituents of the peripheral blood. In several cases studied by Low-Beer and Stone,⁶ however, an absolute monocytosis became apparent reaching in several instances more than 50 per cent of the circulating leukocytes. It has not occurred in the human cases we have studied nor has it been seen in the many animal experiments referred to above.

2. EFFECTS OF FOCALIZED IRRADIATION

In mice exposed to large amounts of β rays from plaques containing P^{32} there was some focalized damage in several organs adjacent to the skin. Changes were very marked in ovaries and testes. But the changes which are of interest in this communication occurred in the spleens of a few of the animals. On the dorsal surface of the spleen there was a zone of severe radiation damage. This zone gradually merged into normal spleen, the gradation consisting of progressively diminishing damage without any evidence of a zone of hyperplasia of undamaged cells. Since the β rays have only a limited range of penetration, it would be expected that near the periphery of their range the small amount of radiation would evoke a stimulating effect if such an effect does occur.

This lack of a stimulating effect at the periphery of an area of focalized radiation is also characteristic of the changes which occur after localized deposition of radioactive isotopes. When these isotopes accumulate in given areas in radiosens-

sitive organs, they produce localized areas of radiation damage—much more extensive with β emitters than with α emitters because of the longer range of the former. The penetration of alpha rays is only a fraction of a millimeter in tissue whereas the β ray penetrates several millimeters. In or near none of these areas of focalized damage is there any evidence of cellular stimulation as evidenced by hyperplasia on normal cells.

With the exception of the highly diffusible Na^{24} , the majority of the isotopes studied tended to localize in bone and most of them also accumulated in the red pulp of the spleen and in other organs. This resulted in a marked hypoplasia and aplasia of the bone marrow. As a consequence, most of the spleens of these animals showed a great increase in ectopic myelopoiesis over the normal. This obviously is in compensation for the aplastic bone marrow. In no instance was a primary stimulation produced in the blood forming tissue which reflected an increase in circulating cells. Compensatory increases were, however, noted in a few instances. The radioisotope, Sr^{89} , is fairly generally distributed to blood forming tissue within the first few days after its parenteral administration. It produces a reduction almost immediately in the nucleated cells of the peripheral blood. It translocates, however, to bone and, therefore, exerts its major effect on the bone and bone marrow. The lymphocytes, however, remain depressed for long periods even though normal lymphopoiesis is resumed in the lymph nodes and spleen. This phenomenon occurs with other isotopes which are not localized more than temporarily in lymphatic tissue.

In some of the rats to which Sr^{89} was administered osteogenic sarcomas developed eight to ten months later. This might be considered as a "stimulation."

DISCUSSION

It is clear from the histologic examination of our animals that there is no evidence of a primary stimulation of hematopoiesis by small amounts of irradiation from either generalized external, or focalized internal sources. The changes in the cells of the circulating blood after irradiation point to the same conclusion, although the analysis is complicated by factors of mobilization and localization in the various parts of the circulatory system. The heterophil increase which follows rather large acute exposures to penetrating radiations is, according to Isaacs,⁵ a hastened maturation of heterophil precursors and thus a "stimulation."

The mechanism of the spectacular monocytosis described by Low-Beer and Stone⁷ in certain of the humans exposed to divided doses of total body x-irradiation is not clear. Since it occurred only in individuals with degenerative arthritis, it may be a response associated with the underlying disease process.

Irradiation of the hematopoietic organs as reflected in changes in the peripheral blood is often stated in the literature to produce stimulating effects. The articles most frequently referred to in this connection are those of Murphy and his co-workers.⁹ Actually these authors stated, 'We have further noted that by one small dose of x-ray we could obtain in a certain proportion of animals a stimulation of the lymphoid elements, preceded by a comparatively short period in which the lymphocytes were below normal.'

Other statements are found in the literature which have affected the conception that x-rays produce a stimulating effect on blood forming tissue. These effects, however, have been described after large doses of penetrating x-irradiation. An increase in the erythrocytes per cu mm and hemoglobin in Gm per 100 ml,¹⁰ an increase in the platelets,^{11 12} reticulocytes,^{13 14} and polymorphonuclear neutrophils¹⁵ have been described by a number of authors. These and other papers on this subject, however, generally dealt with inadequate numbers of control and experimental animals and, therefore, deny statistical validation. Reports are also found in the literature describing the findings in the peripheral blood of man after chronic exposure to ionizing radiation. These reports stress the significance of a lymphocytosis,¹⁶ monocytosis,¹⁷ eosinophilia,^{18, 19} leukopenia,^{19, 20 21} anemia either normocytic or macrocytic.^{22 23} These reports have tended to instill a sense of security in those working with radiation because of the implication that peripheral blood findings could be used as an indication of effect on a given individual even with radiations in the 'tolerance range' (0.1 r total body exposure per day). There is no work to substantiate this. As significant as many of these studies have been, the re-evaluation of these concepts is indicated at this time because of studies conducted on the Plutonium Project in the past few years.

Our findings and interpretations are in accord with the general conclusions of Czepa²⁴ and Packard.²⁵ As the latter points out: "The evidence now at hand points to the conclusion that radiations do not directly stimulate normal activities of the cells, their primary effect is always an injury from which the cell may recover perfectly. But the degeneration products may temporarily quicken the tempo of some normal processes, such as protoplasmic streaming and mitosis, an acceleration which is followed by a retardation and often by very obvious injury. Such reaction is secondary, and is not true stimulation in the sense in which the term is used in radiological literature."

CONCLUSIONS

Extensive studies with acute and chronic application of externally originating ionizing radiations and internally deposited radioisotopes have failed to reveal evidence in the blood forming tissues and peripheral blood of a primary stimulation of hematopoiesis. However, secondary or compensatory increases in certain of the cellular constituents of the peripheral blood were seen and were invariably preceded by a reduction. The initial leukocytosis (heterophil increase) which occurs in the first twenty-four hours after acute exposure to externally originating irradiations is probably a reaction to injury mediated through a mobilization rather than a new formation of blood cells. The abortive rise in heterophils, lymphocytes, and reticulocytes is likewise probably a result of frank injury.

THE EFFECT OF RADIATION ON HEMOPOIESIS IS THERE AN INDIRECT EFFECT?

By JOHN S LAWRENCE, M D , WILLIAM N VALENTINE, M C , A U S ,
AND ANDREW H DOWDY, M D

I. INTRODUCTION

SINCE the discovery of the x-ray by Roentgen, medical science has evinced great interest in elucidating its mode of action. Today, the problem is by no means completely solved. Certain facts, particularly those relating to the results obtained when tissues are subjected to direct radiation, are well established and widely accepted. For example, the aplasia of bone marrow resulting from direct widespread radiation in large doses must be regarded as beyond dispute.

However, there are other observations both of a clinical and experimental nature which are poorly understood and highly controversial. These relate particularly to changes in tissues far removed from the direct site of radiation and have led to the postulation of an 'indirect' action of x-rays. For example, many roentgenologists have privately observed, and others have publicly reported, marked involution of lymph nodes involved in a lymphomatous or metastatic process when radiation was given to other areas sufficiently remote as to have precluded any direct exposure of the former. Equally well known is the marked reduction in the blood count of leukemias treated by x-ray and the leukopenia which develops infrequently in similarly treated nonleukemic individuals, even when supposedly very small areas of marrow are subjected to the effects of direct radiation. These effects, at least in superficial appearance, are not unlike those well established for direct radiation. The result has been a welter of interesting but confusing literature which will presently be reviewed.

It is with this possibility of an "indirect" action of roentgen radiation that this report is concerned. The concept of 'indirect' action requires further definition. It is inconceivable in an organism whose every cell is bathed in a continuous, circulating fluid medium, and which is interlaced with an intricate network of nervous tissue, that such an agent as x-ray, known to be capable of creating extensive destruction of certain cells, should be without an indirect effect. It is well established that there are indirect effects from a thermal burn or mechanical crush. Yet in the case of crush injuries, at least, the only action directly attributable to the causative agent ceases at the time the trauma is discontinued. What occurs in the organism after that must be regarded as strictly nonspecific, even though these events may be of a highly serious nature at times. We, therefore,

From the Departments of Medicine and Radiology of the University of Rochester School of Medicine and Dentistry, Rochester, New York.

This paper is based on work performed under Contract No. W-7-01-eng 49 with the Manhattan Project for the University of Rochester, Rochester, New York. It will appear in Division VI of the Manhattan Project Technical Series as a part of the contribution from the University of Rochester Project, Radiology Division.

have limited our approach to an effort to demonstrate indirect effects *peculiar* to radiation. The pertinent question is whether or not radiation results in the formation of specific substances (not merely those liberated by nonspecific cellular injury or death) which when transported to distant areas produce a characteristic indirect effect.

If such distant indirect effects exist, it seems reasonable that the agents mediating them will in all probability be transmitted to their site of action by way of the circulation. The experimental approach has been, therefore, to arrange for the direct passage of a very large volume of blood for a period of several hours from a radiated to a normal animal, and then subsequently to observe the normal animal for evidence of changes which might be interpreted as indirect radiation effects. Cross circulation by way of carotid to carotid anastomoses satisfies the concept of this approach. Parabiosis, in which small circulatory connections undoubtedly exist between the two animals, was felt to be disadvantageous in that only small amounts of blood cross circulate per unit of time. The methods and technics employed will be described in detail below. Important corollary principles are that the radiated animal must receive a relatively large acute dose of radiation in order that any indirect effect present may be made more manifest, and that sufficient experiments must be done to cover all time intervals up to at least a few days after radiation of the one animal. Significant changes in the leukocyte and lymphocyte picture in the normal animal following cross circulation have been selected as the criteria of an indirect effect in these investigations. These criteria were selected because (1) these elements have been shown to be among the most sensitive indicators of damage by radiation, and (2) changes in these elements and their precursors have been repeatedly mentioned by those attributing indirect effects to radiation.

2. REVIEW OF THE LITERATURE

An appreciable amount of medical literature has accumulated concerning the 'indirect' effects of x-rays. Particularly in the early 1900's many contributions to the subject were making their appearance, the German investigators being especially active in this field. Much of this early literature is mutually contradictory and largely of historical interest. Dosage of radiation administered was in most instances not accurately known, and the quality of radiation employed varied widely from investigator to investigator. Roentgenology was in its infancy and technical factors poorly understood and poorly controlled. Nevertheless, the field is not one that readily lends itself to experimental investigation, and even with vastly increased knowledge and improved technical control, the same general arguments prevailing soon after the turn of the century are still being debated in the literature of the last twenty years.

Broadly these investigations can be grouped into four main types: (1) The demonstration of, or the failure to demonstrate specific toxins (most frequently 'leukotoxins') in the serum of patients or experimental animals exposed to radiation. Both *in vivo* and *in vitro* studies of this nature are reported. (2) The demonstration of, or the failure to demonstrate significant histologic changes in tissues

ordinarily sensitive to roentgen radiation following radiation of some site remote from the tissues studied (3) The clinical demonstration of significant involution of susceptible tissues far removed from the point of application of direct radiation (4) A group of miscellaneous investigations chiefly concerned with demonstration of a wide variety of biochemical abnormalities occurring after radiation, and purported to be the mediators of an indirect effect

Efforts to demonstrate a specific toxin developed as a result of radiation have been particularly numerous Linser and Helber²⁶ (quoted by Capps and Smith) found that a leukotoxin was produced in the blood of organisms exposed to x-ray This leukotoxin when injected into other animals destroyed the circulating leukocytes, and when added to animal exudates containing leukocytes caused loss of motion and degeneration of the cells Curschmann and Gaupp⁷ in 1905 injected into rabbits serum taken before and after radiation therapy from a patient with lymphatic leukemia A few hours after injection the authors observed leukopenia not present in control animals This, they concluded, was due to the development of a specific leukotoxin which could also be demonstrated as capable of destroying human leukocytes in vitro They presented evidence suggesting that such a leukotoxin was inactivated by heat (60 C for one half hour) The following year Klieneberger and Ziepitz²⁰ were unable in their investigations to demonstrate any consistently toxic action of radiated serum on leukocytes in vitro either as to cellular disintegration or as to influence on amoeboid activity In addition no constant leukopenic effect was observed after injection of radiated serum into rabbits The authors concluded no toxin could be demonstrated as a result of radiation Milchner and Wolff²⁹ observed some decrease in leukocytes in animals after the injection of 5 cc of serum from a radiated animal of the same species They also noted some degree of leukopenia when material from a radiated spleen was injected, while injections of normal spleen resulted in leukocytosis However, they felt that their results were not of sufficiently concrete nature to be strong evidence for the presence of a leukotoxin, particularly in view of wide, physiologic variability in the leukocyte counts of the experimental animals used Benjamin⁴ and co-workers after radiating the ears of rabbits with large doses while shielding the remainder of the animal found leukocytosis and lymphopenia occurring, but the blood picture returned to normal within twenty-four hours They claimed to have found increased choline formation in animals after intense radiation, and to have noted that this corresponded to the period of leukocytosis The investigations of Capps and Smith⁶ were interpreted as favoring the concept of a leukotoxin These authors found leukopenia to result from the injection of a few cc of radiated serum from one animal into the abdominal wall of another This serum was also said to cause abnormal destruction of leukocytes in hanging drop preparations With this view Harris¹⁵ concurred, though presenting no experimental evidence of his own

In 1918 Dorn¹⁰ reported that testicular and ovarian atrophy and leukopenia of considerable duration resulted from the injection of enzitol, a borate of choline The author felt that the effects of radiation were exactly reproduced by this substance and that this offered strong support to the concept of choline as the toxic cause of radiation effects Walterhofer³¹ likewise considered indirect effects of

radiation to result from some toxin, possibly choline- In 1922 Billings⁵ in discussing his experiences with the treatment of leukemia by roentgen ray, stated that the application of radiation to any cutaneous surface resulted in the appearance of a leukolytic substance in the blood. The serum of a treated patient dissolved white blood cells in vitro, while the serum of an untreated patient had no such effect. In the same year, Murphy, Liu and Sturm³¹ were forced to conclude that their experiments failed to show any evidence of the presence of a lymphotoxin, even when exposures large enough to effect almost complete destruction of lymphoid tissue were employed. Zacherl¹⁵⁶ four years later, as a result of experiments with radiation of single and parabiotic rats, felt that some toxic substance capable of causing sickness and death of the animals must have been produced. Szilárd⁴⁹ in 1927 could demonstrate no autolytic effect on leukocytes in the serum of radiated leukemics, nor could any such autolysin be demonstrated by complement fixation tests. He could find no increase in choline in the blood or urine of leukemics under x-ray therapy. This author postulated none the less that perhaps electrons circulating in the blood exerted deleterious effects on distant sensitive cells. Strumia's^{47 48} studies led him to conclude sweepingly in 1929 that 'radium emanations, as such, are carried by the blood or that they act through the production of leukotoxins, which are produced by the direct effect of the radium emanations upon the white cells of the blood in superficial vessels, or perhaps upon fixed cells of the reticulo-endothelial system.' He further stated, 'The direct action of radiation upon hemopoietic foci is altogether unimportant. In all cases, the blood acts as a carrier of radiations, either as such or modified, to the hemopoietic foci where its main action takes place.' Woenckhaus⁵⁵ felt that leukopenia observed in normal rats after injection of serum from strongly radiated rats was due to products of proteolysis in the injected serum. However, he also found that when one member of a parabiotic pair was radiated and the other shielded, a *leukocytosis* and not *leukopenia* occurred in the non-radiated parabiont. In 1932, Zwerg⁵⁸ heavily radiated skin flaps in small laboratory animals. The remainder of the animal was shielded, yet if the pedicles connecting the skin flap to the animals remained intact, they uniformly died in two to nine days, and exhibited varying degrees of leukopenia and lymphopenia. The latter, however, were not of the order of magnitude uniformly seen in animals who have received enough generalized radiation to result in death. Zwerg concluded that the effect of roentgen rays on the white blood cell picture is not a direct action on the blood forming organs and probably not on the circulating blood. Rather, he believed, the decomposition of cells gives rise to toxins which in turn damage the hemopoietic system.

Macht^{27 28} in more recent years has attacked the problem by phytopharmacologic methods, examining blood and serum obtained both before and after radiation from a variety of animals. His method, briefly, consists of studying the growth of roots of *Lupinus albus* seedlings in standard physiological solutions as compared with the growth of similar seedlings in similar solutions to which blood or serum had been added. This investigator concluded that there is a toxic substance present in radiated but not in normal serum, and that it reaches its maximum titer twenty-four to forty-eight hours after treatment, disappearing in a few days.

Osgood¹⁶ in 1942 conducted *in vitro* experiments designed to determine if indirect radiation effects on cells of bone marrow could be demonstrated. He set up four human marrow cultures identical in every respect except one received no radiation, in one both cells and medium (35 per cent human serum and 65 per cent balanced salt solution) were radiated, in one *only* the medium was radiated, and in one *only* the cells were radiated. Quantitative hematologic studies indicated no indirect action of radiation on marrow cells suspended in the radiated medium.

A number of histologic studies have also been made in which tissue remote from the direct site of radiation has been examined for evidence of indirect damage. Nakahara and Murphy¹¹ found identical changes in both deep and superficial lymphoid tissue following small doses of soft x-ray. Since 96.8 per cent of the rays did not penetrate beyond a depth of 1 cm. it was felt these changes in deep tissue could not be the result of direct action by the rays. Jolly and Ferroux¹⁹ in histologic studies made on lymphatic structures outside the field of direct radiation were of the opinion that there was grave doubt that the slight changes noted were due to an indirect, toxic action of radiation. Rather it was their inclination to attribute such slight changes as might exist to diffused or secondary radiation. Akaiwa and Takeshima¹ exposed popliteal lymph nodes of rabbits to various amounts of radiation, leaving one side as a nonradiated control. The changes in lymphoid tissue on both sides were noted at a variety of intervals after radiation. The authors concluded that in the control nodes histologic changes identical with those in the radiated nodes occurred, but that the reaction was much less intense and much slower on the nonradiated side. In 1940, Hsu and Ma¹⁶ radiated one femur only of rats with doses varying from 1000r over a four day period to 5000r over a forty day period. The day after the course of radiation was complete animals were sacrificed and the bone marrow of radiated and nonradiated femurs, the submaxillary lymph nodes, and the spleen of each were examined. In the nonradiated hemopoietic tissues changes of a *hyperplastic* nature interpreted as compensatory, were noted. Le Blond and Segal²⁵⁻⁴² found large doses of roentgen rays produced secondary changes in well shielded organs far distant from the point of impact. These consisted of constant thymus and generalized lymphatic atrophy and adrenal hypertrophy and frequently of fatty infiltration of the liver and ulcerations of the stomach. Such lesions were considered part of a general intoxication following radiation and were felt to be similar to those described by Selye as occurring in the nonspecific "alarm reaction" developing after the application of a wide variety of injurious stimuli. It is interesting (as has been noted with other noxious agents capable of eliciting an "alarm reaction") that thymus and lymphatic atrophy was suppressed by adrenalectomy but the gastric lesions and general lethal effects of the rays increased. Barnes and Furth³ in 1943 using single and parabiotic mice reported an extensive series of investigations. These authors examined bone marrow, lymph nodes, and spleen in unexposed areas of mice radiated with anywhere from 400r to 7000r. Some histologic changes were observed, but these were slight and regarded as probably the result of products of damaged tissue transported by way of the circulation. The degree of change depended on the dose of radiation and probably on the volume of tissue radiated. The authors observed similar histologic

changes in mice burned under anesthesia with the actual cautery over the chest and abdomen, and in the lymph nodes of two mice dying of iodoacetic acid poisoning. In addition, the effect on the hemopoietic tissue and lymph nodes of normal mice whose parabionts had been subjected to radiation was studied. Histologic changes similar to but much less extensive than those found in the radiated animal were observed in the tissues of the nonradiated parabiont. These were considered non-specific. Densted,⁹ likewise in 1943, reported on a large number of examinations of bone marrow and peripheral blood in patients being treated with x-ray. Control specimens were obtained before treatment. The majority of the patients were suffering from malignant disease, and x-ray dosages, while variable, were for the most part cancericidal in magnitude. Marrow specimens were obtained a considerable distance away from the sites exposed to direct radiation. Twenty-eight patients developed no granulocytopenia (below 3000 granulocytes per cubic millimeter). In these there was no abnormality of the nonradiated marrow either as regards total quantity of cells or differential values. In 20 patients the granulocytes of the peripheral blood fell below 2300 per cubic millimeter. In these cases, the cellularity of the nonradiated marrow remained normal, but adult polymorphonuclear leukocytes in the marrow decreased from an average of 16 per cent in control groups to 6.5 per cent in granulocytopenic groups. The promyelocytes were unquestionably increased. For these reasons, the author concluded there is in certain patients some degree of maturation inhibition in myelopoiesis, and that this is probably due to some toxic or anaphylactic factor. He considers this to be an indirect effect of roentgen and radium rays on hematopoiesis and suggests it may occur more readily in patients who are in poor condition.

While many roentgenologists have observed phenomena suggestive of an indirect radiation effect, relatively few have seen fit to publish these clinical observations. However Langer²³ has stated that he had observed indirect radiation effects on several occasions. He cites the case of a boy treated with x-ray for verruca simplex of both hands. Although only one hand was treated the warts gradually disappeared from the untreated hand. He refers also to a case reported by Baensch in 1922 where, in a patient with primary carcinoma of the breast, regional nodes disappeared even though shielded with lead rubber during radiation. Scott⁴¹ has reported to have observed frequently in cases where large areas were radiated the disappearance of lymphosarcomatous glands in regions receiving no radiation. In one case, he states, this was manifest within half an hour after therapy.

In addition to the above, a miscellany of diverse mechanisms have been postulated as the mediators of indirect radiation effects. In 1905, Musser and Edsall³² concluded that the effect of x-ray is not direct but is dependent on a reaction of the body subsequent to exposure. They felt that the increased catalysis observed after radiation was a response in the form of an increased fermentative process, and concluded that favorable results to x-ray therapy could occur only when the body was capable of such response. Demiéville⁸ concluded that an indirect effect of radiation, probably conditioned through decomposition products, was exhibited in the blood-forming organs. Petersen and Saelhof³⁸ in 1921 demonstrated increased serum titers of several enzymes after radiation and speculated whether some remote effects of

radiation may not be due to enzyme mobilization. Hussey¹⁷ found an uncompensated alkali excess in rabbits exposed to x-rays and suggested alteration in acid-base balance may be an important factor in their action. Opitz¹⁸ suggested that toxins produced by x-rays may be agglutinated by tumor cells, thus impairing tumor growth. Rahm and Kooser¹⁹ assumed chemical changes are initiated in the dead interstitial substances of the body and that these may be responsible for the end effects seen. V. Pannewitz²⁰ observed acidosis followed by slowly increasing alkalosis which persisted for several days after radiation. Kluge and Zwerg²¹ have suggested that mobilization of hormones, particularly those of the hypophysis, are important in producing the observed effects of radiation. Selye¹⁶ in an extensive review of general adaptation phenomena has pointed out that many of the metabolic changes described after radiation such as hyperglycemia, decrease in blood cholesterol, increase in ketone bodies in the blood, elevation of the NPN, and disturbances in acid-base balance are seen with equal frequency as a response to many injurious stimuli such as traumatic shock, exposure to cold, burns, drugs, and solar rays. This author feels such things represent nonspecific systemic phenomena elicited by injurious stimuli to which the organism is qualitatively or quantitatively not adapted. Very recently Dougherty and White¹³ have proposed that roentgen radiation exerts both a direct and indirect effect on lymphocytes and that the indirect action can be explained on the bases of the increased pituitary—adrenal cortical activity caused by radiation.

It is readily apparent that the literature weighs heavily on neither side of the question.

3 EXPERIMENTAL TECHNIC AND METHODS

The experimental animal employed was the cat and the chief experimental device cross circulation by way of carotid to carotid anastomoses. In the twenty-six successful cross circulation experiments which form the basis of this report, a normal animal was in each instance cross circulated with a radiated animal. The latter received its radiation either during the actual time of cross circulation or at varying intervals prior to its establishment. A control group in which normal cats were cross circulated had already been established in this laboratory in connection with experiments previously reported.²⁴

The technic of establishing cross circulation was as follows. The animals were anesthetized with nembutal administered intraperitoneally. The operative site was prepared, and the carotid artery of each on one side isolated and dissected free. A small rubber covered clamp was placed at the proximal and distal ends of the freed vessel and the artery divided midway between the two clamps. Both segments were then washed free of blood with isotonic citrated saline solution. In each animal, the proximal arterial segment was cannulated by threading it through a Monel cannula, everting the cut end of the vessel over the outside of the cannula, and tying with fine 5-0 catgut. The two animals were next brought together in such a way that the proximal arterial segment of each was directly adjacent to the distal segment of the other. They were conveniently supported in this position by the use of small sandbags. A bed for the anastomoses was readily formed by sutur-

ing together the strap muscles of the two animals. Following this, the distal arterial segments were drawn over the outside of the cannulated proximal segments and tied about the cannula. Clamps were then released and cross circulation allowed to function from two to ten hours. The cross anastomoses thus established afforded a continuous endothelial pathway by which the blood from each cat supplied one side of the head of its partner and vice versa. Figure 1 diagrams the method of anastomosis.

The volume of blood traversing an anastomosis of this type, will, if uncompensated, result in the exsanguination of an animal within a few minutes. At the conclusion of the period of cross circulation the patency of each connection was always tested *in situ* by reapplying the clamps, dividing the anastomoses *distal* to each cannula, and releasing the clamps for a brief instant.

Prior to an experiment, control hematologic studies consisting of hemoglobin determinations and a total and differential white blood cell count were made. Only animals which were clinically well and which showed no gross hematologic abnormalities were used. During the period of cross circulation leukocyte counts

FIG. 1. Diagram of end to end carotid to carotid anastomosis of the type employed in these experiments.

and smears were made at approximately hourly intervals. In each instance blood was obtained from the marginal ear vein. The hematologic follow-up of the non-radiated animal consisted of a minimum of daily (except Sunday) total and differential white blood cell counts for a period of two weeks and similar studies made every other day for a period of approximately an additional two weeks. All counts were made with Bureau of Standards certified pipets. All blood smears were made by the coverslip method and stained with Wright's stain.

The radiation to which one member of each cross-circulated pair was subjected was kept constant and subject to the following factors:

Total Dosage	1500 r whole body radiation
Voltage	k v p 250
Milliamperage	15
Target Distance	22 inches to center of cat
Filter	Aluminum parabolic plus $\frac{1}{2}$ mm copper
Half Value Layer	2.1 mm copper
Rate of Administration	Approximately 25 r per minute with slight variation

This amount of radiation invariably results in the death of cats within four to seven days

In the majority of experiments, one animal was radiated at some interval prior to cross circulation. In seven experiments, however, cross circulation was first established and then one animal radiated while the other was shielded. Shielding was accomplished by means of an appropriately shaped wooden frame covered with one-fourth inch of lead plate. An ionization chamber placed under the frame recorded the small amount of scatter radiation which escaped the shielding. This varied in different experiments from a minimum of 20r to a maximum of 43r.

It was customary to administer isotonic saline subcutaneously to both animals during cross circulation and at its conclusion. In some instances, penicillin in saline was also administered.

4 PRESENTATION OF DATA

In all, twenty-six successful cross circulation experiments were performed. Of these, all the normal animals except one were followed hematologically for a period of approximately twenty-eight days after return to their own circulation. Cat number 153 had to be sacrificed about two weeks after cross circulation because of a wound infection. With one exception, each cross circulated team consisted of one radiated and one nonradiated member. The experiment involving normal cat number thirty-six who was cross connected in series with two radiated animals simultaneously constituted this exception. In such a circuit, blood from the normal animal passed to one radiated animal, which in turn was connected to a second radiated animal, which likewise in turn supplied blood to the normal cat.

The data pertinent to these experiments are especially suited for presentation in graphic and tabular form and this has been the mode of presentation selected.

Figure 2 shows in graphic form the duration of cross circulation and the interval after radiation of one member of the team that cross circulation was established. It can readily be seen that in the majority of experiments the duration of cross circulation was in the neighborhood of eight hours. A few animals were cross circulated as long as ten hours, one for as little as two hours and seven minutes. The group of animals in which radiation of one partner took place at the time the cross circulation was functioning were connected for approximately three to five hours. More experiments were performed during or shortly after the radiation of one member because it was felt that logically the most profound effects on the normal partner could be expected under these circumstances. Nevertheless, all the time intervals after radiation up to eighty-two hours were covered.

Table 1 presents detailed hematologic data from each experiment and indicates the total leukocyte and absolute lymphocyte count of each normal animal before and at varying intervals after cross circulation with a radiated partner. The intervals selected were done so arbitrarily with an eye to conserving space without sacrificing a comprehensive and representative presentation of the data. In addition, in the experiments in which one animal was shielded and the other radiated during the period of cross circulation, the amount of radiation recorded by the

ionization chamber under the shield has been indicated. In every experiment of this type a small amount of scatter radiation escaped the shielding.

Tables 2 and 3 give the means and standard deviations for total lymphocyte and leukocyte counts respectively of the normal animals for the same time intervals before and after cross circulation as given for the individual animals in table 1. The figures are divided into three groups: those applying to the shielded group of normals, which were cross circulated at the time of their partner's radiation, those applying to the non-shielded group which were cross circulated with a previously radiated partner, and those applying compositely to the group as a whole. It will be noted that the number of animals for which data are presented varies somewhat on different days in the tables. This is due to the fact that counts were made but six

FIG. 2. Each black line indicates the duration in hours of cross circulation in a single experiment. The time interval after radiation of one member that cross circulation was established is also indicated.

days a week so that at any specified interval after cross circulation it is possible that counts are not available for every member of the group.

Figure 3 indicates graphically a composite picture of the average leukocyte and lymphocyte counts of the entire group during the period of follow-up. In addition, the same data on the seven shielded animals are graphed separately, both because these animals unavoidably received small amounts of radiation, and because this type of experiment was considered the most critical of the group.

5 RESULTS

Analysis of the data indicates few or no detectable hematologic abnormalities in the normal cat at any time after its cross circulation with a radiated animal.

TABLE 1.—Total Leukocyte and Absolute Lymphocyte Count Per Cubic Millimeter of Twenty six Normal Cats Following Cross Circulation with Radiated Animals

N = Number of animals on which counts are available at the time specified in column 1

The average leukocyte count for the entire normal group and for the critical group in which cross circulation was established at the time of radiation of their partner remains throughout the entire approximately twenty-eight day period of follow-up actually somewhat higher than the pre-cross circulation control level. In not even a single animal did evidence of significant leukopenia develop at any time during the experiment — this despite the fact animals received for a period of several hours the full volume output of the carotid artery from a radiated partner. As would be expected, well marked leukocytosis was present in many instances for a few days after the operative procedure. Its duration varied rather widely from

N = Number of animals on which counts are available at the time specified in column 1

FIG 3 Average leukocyte and lymphocyte counts per cubic millimeter of the whole group of animals for the entire period of the experiment are indicated. The average leukocyte and lymphocyte counts for the critical shielded group are graphed separately.

animal to animal. Of some interest is the very striking degree of leukocytosis developing at the time of cross circulation in certain animals whose partners had received their radiation at the time of or shortly before cross circulation. Whether these more striking instances of leukocytosis are due to the passage of leukocytotic

metabolites resulting from tissue breakdown as a result of radiation cannot be said with certainty. The leukocyte counts in question were markedly in excess of those developed in a normal control group, however.

Individual lymphocyte values found in normal animals after cross circulation show a moderate amount of variation. As would be expected during the period of marked leukocytosis during the few days immediately following cross circulation, a drop in the absolute lymphocyte count was noted. Lymphopenia is a well known companion of neutrophilic leukocytosis and in this instance, it was presumably accentuated by the fact some animals had been cross circulated with partners who had no circulating lymphocytes at all. To be sure, the average lymphocyte level for the entire group remained throughout slightly lower than that found before cross circulation and this trend was slightly more apparent in the critical shielded groups as a whole. In view of the physiologic variations in lymphocyte counts, in view of the persistence of some *increase* in the average total leukocyte counts throughout the experiment, and more particularly in view of the fact that the reduction in lymphocyte count was relatively slight and not at all of the order of magnitude associated with direct radiation, there is grave question that any significance can be attached at all to this finding. At no time did the average per cent of lymphocytes fall below 4.9 per cent of the leukocytes present even in the shielded group, and this figure was obtained only for the first day after radiation. In all other instances it was appreciably higher than this.

6 DISCUSSION

It is apparent that under the conditions of our experiments, no specific "indirect" effect of radiation has been demonstrated. It is also felt that if significant indirect effects peculiar to radiation are dependent upon the circulation, they should have been readily demonstrated by the experimental setup employed. However, it cannot be denied that had it been possible to maintain cross circulation for much longer periods—say forty-eight or seventy-two hours instead of eight to ten hours—indirect effects too slight for demonstration during the shorter period might have become manifest. The possibility of an indirect radiation effect mediated solely by the lymphatics has also been considered but discarded as highly unlikely. Any lymphatic disseminated agent would in all probability soon reach the venous and arterial tree and would be expected to manifest itself in the blood. Further, if in some devious manner it should be removed from lymph before reaching the blood, indirect effects of radiation would exist purely in the regional lymphatic drainage area of that portion of the body directly radiated. The existence of such a purely localized regional indirect radiation effect is supported by no evidence and, in fact, is contrary to whatever evidence there is suggestive that such indirect effects exist.

It is also apparent that there is no satisfactory evidence for a *characteristic* indirect radiation effect presented in the medical literature. Such evidence as is presented is of dubious character and refuted for the most part by contrary results obtained in similar types of experiments by other investigators. Nor has there been more than a desultory attempt on the part of investigators of indirect radiation effects to

differentiate body reactions common to a variety of damaging stimuli from those specific to radiation. This is a fundamental differentiation, particularly in view of Selye's now well supported observations that an identical, nonspecific systemic reaction (at times severe enough to result in death) occurs as a response to many unrelated injurious stimuli. Still, it is undoubted that leukopenia develops in a certain number of individuals treated with roentgen radiation even when the amount of marrow directly exposed to radiation is thought to be minimal. It is also highly likely that involution of and histologic changes in normal and abnormal lymphoid tissue remote from the site of direct radiation as observed by many roentgenologists and research workers is real and not apparent. It would seem wise to examine these considerations more closely to see if it is necessary to assume they are peculiar to radiation and if they can be accurately described as *specific* attributes of radiation per se.

Kornblum²² and his associates in an extensive series of clinical observations concluded that therapeutic radiation tended to lower the leukocyte count. However, in approximately one-half of the patients studied there was no decrease in the number of neutrophils and in the great majority of the remaining cases depression was of slight degree. In but 7 cases out of 120 were the neutrophils reduced below 2000 per cubic millimeter. The effect of therapeutic radiation on the lymphocytes was more striking, a definite decrease in their numbers being the rule. In most cases the drop in count was relatively slight but in some instances it was very pronounced. It is thus seen that leukopenia of appreciable degree is an inconstant feature of radiation therapy applied to areas where there are no or minimal amounts of hematopoietic tissue. While the area treated, the volume of tissue radiated and the total amount of radiation are, in our opinion, all of importance as regards the production of leukopenia, yet it is impossible to predict accurately in most instances of local radiation over essentially non-hematopoietic areas which individuals will and which will not develop leukopenia. On the other hand, one can always anticipate the development of leukopenia when radiation is given over any appreciable amount of hematopoietic tissue such as in total body irradiation. Further, leukopenia associated with total body irradiation is more marked than when no or minimal amounts of hematopoietic tissue are radiated. Thus radiation over large amounts of active bone marrow can be expected to produce marked leukopenia, whereas radiation over non-blood forming areas produces mild, if any, leukopenia. Still another difference between the results of radiation over hematopoietic and nonhematopoietic areas is to be found in the morphological appearance of the bone marrow. With radiation directly over the bone marrow, hypocellularity and/or aplasia result, whereas the marrow shows normal cellularity or it may even be hyperplastic when other tissues are exposed and it is excluded.

Three possible explanations for these differences arise. First, they may be only quantitative, the so-called indirect effect actually being a direct effect resulting from inclusion of larger amounts of hematopoietic tissue in the field of radiation than generally considered to be the case. It should be noted in this connection that the exact amount of hematopoietic tissue exposed to radiation is not known in

many instances where an indirect effect is said to occur. It may well be that the amount of blood producing tissue radiated in these cases is sufficient to reduce the output of blood cells to a point where their normal level cannot be maintained. In particular, one must consider the possibility that in debilitated patients the reserve for production of blood cells may be distinctly lower than in the normal. If this is true, the inclusion of even small amounts of hematopoietic tissue in the radiated field in patients receiving radiation therapy would be of much greater significance than ordinarily considered since most of such patients are suffering from malignancy or some other serious disorder which is associated with debilitation. As a further indication that the effect may be due to inclusion of hematopoietic tissue in the radiated field is the well established fact that the leukopenia practically never results from radiation of the head in which case radiation can be given without inclusion of more than minimal amounts of active bone marrow. Second, a specific indirect effect of radiation may exist, i. e., some substance or substances may be produced directly and characteristically by radiation and then transmitted to parts of the individual that were not exposed to radiation. Our experiments have failed to reveal such a situation. Third, a nonspecific effect of radiation may occur, that is, radiation over a local area may produce certain nonspecific changes in the tissues exposed. As a result of these nonspecific effects histological changes may develop in some unexposed tissues and leukopenia possibly be produced also. It is again possible here that the nonspecific effects may be greater in a debilitated than in a normal individual. Our experiments have failed to show the presence of any nonspecific substance capable of producing leukopenia. We have not examined the tissues histologically but feel that the evidence in the literature is sufficient to justify the assumption that these nonspecific histologic changes did occur at least in the normal animals which were being cross circulated at the time their partner was irradiated.

Substantial involution of lymphoid tissue not itself directly injured has been frequently observed as a nonspecific response to a wide variety of injurious agents. Bardeen² in studying visceral changes occurring in patients dying of superficial burns noted striking histologic changes of a degenerative nature in lymphoid tissues and commented on the similarity of these changes to those found experimentally after injection of ricin or diphtheria toxin. These widespread alterations in all the lymphoid organs of the body following burns have been amply confirmed by other investigators.^{52, 37, 3} Similar changes and transient leukopenia and lymphopenia have been observed in mice subjected to dry heat in nonfatal exposures.^{30, 33} Selye^{43, 44, 45} in what he has chosen to term the "alarm reaction," has described striking involutionary and degenerative changes in all the lymphatic organs as a nonspecific response to a variety of insults (cold, heat, surgical shock, drugs). Nonspecific damage apparently may result in atrophy of the spleen beginning in the center of the Malpighian corpuscles, marked loss of weight of thymus and lymph nodes, and, at times even complete disappearance of germinal centers in the latter. Zechwer⁵⁷ noted similar changes after injuring subcutaneous tissues by injection of formalin. It is interesting that this involution of lymphoid structures does not occur in the adrenalectomized animal—particularly in the light

of recent investigations suggesting that lymphoid structures and possibly the lymphocytes may in some way be affected by the administration of adrenal cortical hormone^{18 11 12 46 53 54 40 14} In view of the above observations, it is possible that x-ray is merely one of many injurious agents capable of producing generalized involution of lymphoid tissue as a nonspecific response to local injury This, of course, is not to be confused with local involution and degeneration of lymphoid tissue directly exposed to radiation

The question of whether or not a specific indirect effect of radiation exists must be regarded as unsettled It is our feeling that leukopenia, when it results from radiation, is probably due at least in part to direct exposure of some of the hemato-poietic tissue Other factors which may be operative are the general physical status of the patient, nutritional disturbances resulting from the effects of radiation to the gastrointestinal tract, general radiation sickness, and the amount and degree of total body irradiation resulting from scattered radiation We also feel that morphologic changes occur in certain nonexposed tissues (e g , lymph nodes, and thymus) We are not convinced, however, that these nonspecific changes produce leukopenia

7 SUMMARY

1 The general aim of the investigations here reported has been to obtain evidence for or against "indirect" radiation effects

2 To this end, twenty-six successful cross circulation experiments (carotid to carotid anastomoses) have been performed between normal cats and radiated cats

3 Cross circulation was established in most instances at some specified time interval after the radiation of one partner All intervals up to eighty-two hours after radiation of one partner were covered

4 In seven experiments cross circulation was established and then one animal radiated while the other was shielded These were considered the most critical experiments of the group

5 Detailed data on leukocyte and lymphocyte counts in the normal animals obtained during an approximately twenty-eight day period of follow-up are presented

6 These data are not considered to support the thesis of indirect effects peculiar to radiation A trend toward slightly lowered absolute lymphocyte counts in normal animals after cross circulation was not considered significant, and in no instance did leukopenia develop in the normal animal

7 The literature is reviewed and discussed

NORMAL BLOOD COUNTS IN DIFFERENT SEASONS

By J ENGELBRETH-HOLM, M D , AND AA VIDEBAEK, M D

BLOOD counts, like various other routine examinations, were introduced into clinical medicine a rather long time before their physiologic variations and the ranges of their normal values had been finally determined. Hence, all statements of leukocyte counts and differential counts in normal individuals suffer from want of uniformity. Sex and age, and perhaps even race must be considered. Exercise and excitement bring about a conspicuous increase of the number of leukocytes,¹ whereas variations due to static changes are less significant.² The alleged "digestive leukocytosis" has not been confirmed by modern investigations.³ Further diurnal rhythms of the neutrophils have been noticed,⁴ presenting a climax in the afternoon and shortly after midnight. Likewise, rhythmical variations have been observed showing maxima and minima within about one hour.⁵ According to Friedlander and Wiedemer,⁶ the number of reticulocytes rises conspicuously during the months of spring, dropping to a low in the autumn, whereas, inversely, the hemoglobin and the number of erythrocytes show the lowest values during spring. Further, these authors have stated that heliotherapy is followed by a rise in the number of reticulocytes, they therefore suggest that seasonal variations in the reticulocyte count must be due to changes in the intensity of sunlight.

In order to decide whether results of routine blood examinations are subject to seasonal variations worth mentioning, we have carried out examinations four times during one year (in the months January, March, June and October) on 40 male and 29 female healthy students of medicine determining the hemoglobin per cent (Haldane), the number of erythrocytes and the number of reticulocytes (per one thousand erythrocytes), and the sedimentation rate, counting, in addition, white cells and eosinophils (Dunger), and making differential counts of 300 cells on cover glass smears. The examinations were performed in the morning on venous blood, after half an hour of muscular rest, all the tests being examined by the same person.

The hemoglobin value for both sexes drops to its lowest in October, the difference being statistically significant, reduction of the average figures is about 10 per cent, equally, the color index seems to be lowest in October, the number of erythrocytes, however, being constant. The highest reticulocyte numbers are found for both sexes in the most sunny periods of the year, the deviation being, however, not significant, whereas the sedimentation rate is found to be lowest in June and highest in October for both sexes. The white cell count and that of their fractions present great variations although the averages vary but slightly and insignificantly, it must, however, be kept in mind that the choice of the four months of examination has been arbitrary, and contingent maxima might fall outside these periods.

The results present a conspicuous variation especially from one individual to another at a given time of the year, whereas variations in the same person examined

From the "Finsen-Laboratorium" and the University Institute of Pathological Anatomy, Copenhagen

TABLE 1.—The maximal and minimal findings, and the average values of blood counts made on 40 males and 29 females at different times of the year

	January	March	June	October
Average number for 40 males				
Hemoglobin (per cent)				
Erythrocytes (millions)	100 (112 - 90)	97 (106 - 87)	99 (110 - 87)	89 (99 - 78)
Color index	5 06 (5 96- 4 57)	4 94 (5 50- 4 41)	5 00 (5 58- 4 50)	4 96 (5 56- 4 28)
Reticulocytes	0 99 (1 07- 0 88)	0 98 (1 07- 0 87)	0 99 (1 08- 0 91)	0 90 (0 97- 0 75)
Sedimentation rate	4 2 (15 - 1)	4 2 (10 - 1)	5 8 (18 - 1)	4 6 (10 - 1)
White cells	2 6 (6 - 1)	2 5 (10 - 1)	2 2 (6 - 1)	3 0 (5 - 1)
Neutrophils	5830 (9440 - 3500)	5700 (117,000 - 3320)	6050 (12,000 - 3400)	5900 (9080 - 3480)
Eosinophils	3150 (6600 - 1520)	3160 (6520 - 1300)	3580 (5760 - 1400)	3280 (6850 - 1090)
Lymphocytes	215 (480 - 72)	194 (450 - 90)	204 (510 - 51)	235 (480 - 60)
Monocytes	1900 (2610 - 995)	1800 (2520 - 1200)	1690 (2600 - 980)	1790 (2600 - 1260)
	550 (970 - 140)	520 (1010 - 120)	530 (725 - 360)	560 (690 - 250)
Average numbers for 29 females				
Hemoglobin (per cent)				
Erythrocytes (millions)	86 (100 - 70)	84 (97 - 95)	84 (95 - 74)	77 (89 - 72)
Color index	4 41 (5 10- 3 76)	4 40 (5 30- 3 82)	4 32 (5 01- 3 75)	4 24 (4 75- 3 78)
Reticulocytes	0 97 (1 07- 0 79)	0 95 (1 07- 0 84)	0 97 (1 06- 0 90)	0 91 (0 99- 0 80)
Sedimentation rate	4 5 (13 - 1)	3 4 (10 - 1)	5 0 (11 - 1)	4 7 (10 - 1)
White cells	5 2 (11 - 2)	4 5 (8 - 1)	3 6 (10 - 1)	5 5 (10 - 3)
Neutrophils	5620 (8120 - 3640)	5430 (7440 - 3520)	5380 (7600 - 3940)	5570 (7480 - 4140)
Eosinophils	3210 (6100 - 1530)	3170 (5380 - 1690)	3220 (5410 - 1920)	3130 (4530 - 2050)
Lymphocytes	162 (300 - 30)	176 (422 - 61)	179 (389 - 53)	169 (360 - 50)
Monocytes	1740 (2770 - 1040)	1580 (2680 - 1100)	1490 (2080 - 1140)	1740 (2430 - 1270)
	510 (760 - 250)	480 (880 - 270)	450 (820 - 240)	510 (1070 - 250)

at different seasons are less pronounced. This indicates that physiologically some individuals have a high, and others a low leukocyte level. The averages for the 40 males and 29 females examined at different seasons will be seen in table 1. The seasonal variations which have been observed are less pronounced than the individual variation at a fixed time of the year, in other words the seasonal variation is without significance to the estimation of the results achieved by common blood counts. The present figures, thus, yield a basis of evaluation of the normal average values for adult men and women. The results may be seen from table 2, showing further the maximal and minimal findings, the marked standard deviation is illustrated in figure 1. Since each leukocyte group may present relatively high per cent values even with a low leukocyte total, and vice versa, there can be ascribed no special importance to the cell percentage which must be considered only as an aid to

TABLE 2.—*The maximal and minimal findings, and the average values of blood counts made on 40 males and 29 females at different times of the year*

	Men			Women		
Hemoglobin (per cent)	96	(78 - 112)		82	(70 - 100)	
Erythrocytes (millions)	4.99	(4.28 - 5.96)		4.35	(3.75 - 5.30)	
Color index	0.97	(0.75 - 1.08)		0.95	(0.79 - 1.07)	
Reticulocytes	4.7	(1 - 10)		4.4	(1 - 13)	
Sedimentation rate	2.6	(1 - 10)		4.6	(1 - 11)	
White cells	5870	(3320 - 12,000)		5500	(3520 - 8120) ¹	
Neutrophils	3310	(1090 - 6850)		3190	(1530 - 5820)	
Eosinophils	210	(51 - 510)		170	(30 - 412)	
Monocytes	540	(117 - 1014)		490	(240 - 1070)	
Lymphocytes	1800	(980 - 2610)		1640	(1040 - 2770)	
Neutrophils (per cent)	55.0	(38.7 - 74.5)		57.4	(42.4 - 75.7)	
Eosinophils (per cent)	3.4	(0 - 10.0)		2.9	(0.5 - 8.0)	
Monocytes (per cent)	9.4	(4.0 - 14.0)		8.9	(5.3 - 14.3)	
Lymphocytes (per cent)	31.6	(11.3 - 47.0)		30.0	(15.0 - 45.0)	

the estimation of the absolute number of the different white blood cells. A lymphocyte per cent of about 50, thus, may very well be normal, but this is conclusive only when the absolute number is to be found within the ranges of 1000-3000. The lines drawn by Naegeli and Schilling,^{5, 8} 20-25 per cent and 21-35 per cent respectively, therefore, must be considered too narrow, whereas the absolute figures come up very well to the statements given by, e.g., Boerner,¹ Schilling,⁸ and Saltzmann.⁷ It is, however, worth mentioning that the upper normal range of monocytes and eosinophils is 1000 and 500 respectively. According to the above examinations, the normal values for adult men and women are

White cells	3,000-10,000 per cu. mm. of blood
Neutrophils	1,000-6,000
Eosinophils	50-500
Monocytes	100-1,000
Lymphocytes	1,000-3,000

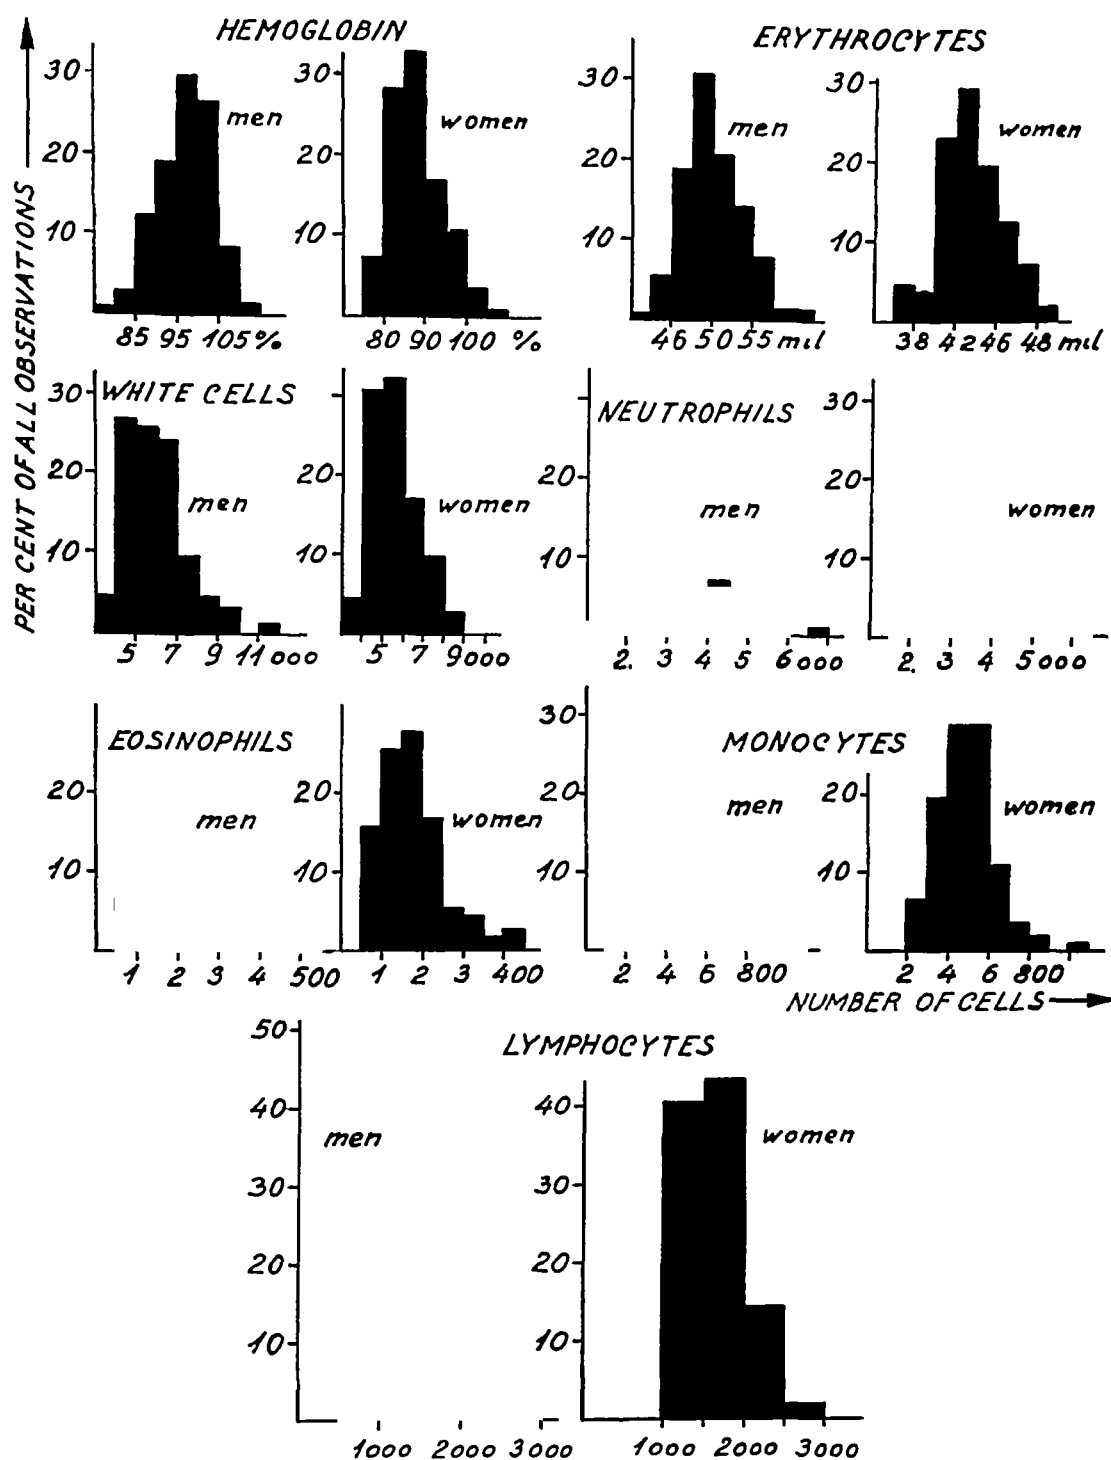

FIG 1. SHOWING BLOOD COUNTS FOR 40 MEN AND 29 WOMEN EXAMINED
FOUR TIMES DURING ONE YEAR

The diagrams show the percentage of all observations occurring within the different intervals

SUMMARY

Report is given of examinations carried out on 40 healthy males and 29 healthy females in the months of January, March, June and October, with determination of

the hemoglobin, the number of erythrocytes and reticulocytes, the sedimentation rate, the white cell and differential counts. The hemoglobin value appears to be lowest in October, the number of reticulocytes highest in June, the sedimentation rate lowest in June. The remaining figures present no exact seasonal variations. Some individuals have a high leukocyte level, others a low one. Normal values are illustrated.

JUNE, 1948

EXOGENOUS HEMOCHROMATOSIS RESULTING FROM BLOOD TRANSFUSIONS

By STEVEN O SCHWARTZ, M D , AND SUNOLL A BLUMENTHAL, M D

HEMOCHROMATOSIS was first described by Hartman and Chausser in 1882 as "bronze diabetes" because of the association of skin pigmentation with diabetes mellitus. Von Recklinghausen in 1889 showed that the pigmentation of the skin and viscera was due to deposits of hemosiderin and hemofuscin. Hemochromatosis was considered quite rare, being clinically diagnosed only three times in 160,000 admissions to the Johns Hopkins Hospital, and on postmortem examination only four times in 5,000 autopsied cases at the Bellevue Hospital. There were less than 100 cases in the literature before 1920. By 1935, Sheldon⁴³ was able to collect 311 acceptable cases and at the time of the last complete review of the literature in 1941⁴ there were 436, indicating either a growing incidence or, more likely, a keener awareness and consequently more frequent recognition of the disease.

Classically, hemochromatosis occurs in the male, the ratio being 295 males to 16 females in Sheldon's series. It is practically unknown before the age of 20 and has its peak incidence between 45 and 55 years. The fully developed disease presents (a) an enlarged liver (caused by a hypertrophic cirrhosis), (b) a bronze pigmentation of the skin, which usually has a peculiar slaty blue or metallic appearance,¹³ (c) diabetes mellitus of a severe type, and (d) a form of sexual hypoplasia characterized by impotence and an alteration of the hair distribution.²⁷ However, one or more of these features may be absent.²⁴ Pathologic characteristics are (1) the pigment deposition, (2) the fibrotic changes, (3) the cellular degeneration in certain of the parenchymatous organs, this being the least prominent. The disease is inevitably fatal, death resulting either from the diabetes or from cirrhosis of the liver. The life expectancy in Butt and Wilder's⁶ series varied from one month to 13 years, averaging one and one-half years from the time the diagnosis was made. Sheldon puts the figure considerably higher, stating that the average terminal period is 18½ years.

Anemia is very rare in hemochromatosis, the average blood values being 4.1 million red cells and 80 per cent hemoglobin.

The two kinds of pigment found in hemochromatosis are hemosiderin and hemofuscin. Hemosiderin is an iron containing pigment, deep yellow in color, the particles varying in size from fine granules to larger masses which may be visible to

From the Hematology Laboratory and the Hektoen Institute for Medical Research of the Cook County Hospital, Chicago, Illinois

Aided by a grant from the Wilson Laboratories

the naked eye Hemosiderin contains about 55 per cent iron Its reactions are not typical for ferric iron and there is no reaction for ferrous iron Cook⁹ considers it to be some form of colloidal ferric oxide physically combined with an organic substrate Hemosiderin is the predominating pigment of hemochromatosis and has an extreme affinity for gland cells of both external and internal secretion The greatest amounts are found in the liver and pancreas, but there is no secreting gland in the body that may not be affected Striking exceptions to involvement are the kidneys and the germinal epithelium of the testes The former has only a moderate degree of pigmentation, confined in most cases to the convoluted tubules of the second order, while the latter usually escapes altogether Striated muscle is, but smooth muscle is not affected In at least 90 per cent of the cases, the heart muscle is pigmented, often by large amounts Considerable quantities of pigment are found in the reticulo-endothelial system They occur in the Kupffer cells of the liver, the alveolar endothelium of the lung, and in the spleen In structures where there is much pigment in the tissue cells, there is almost always pigmentation of the connective tissue as well, this being especially so in the liver and pancreas

Hemofuscin is a dark, almost black, pigment which contains no iron It contains about 3.7 per cent sulphur and is probably related to melanin In hemochromatosis it occurs to a slight extent in the epithelial cells of the glandular organs, but with more frequency in the connective tissue, especially that of the spleen There is nearly always a large quantity in the heart muscle, but its site of election is the smooth muscle of the genital and alimentary tracts, and the smooth muscle of arteries

An invariable feature of the disease is cirrhosis of the liver, usually of the hypertrophic type The pancreas is also constantly affected, though usually less severely In contrast to the changes which occur in the liver, pigmentation and cirrhosis do not always go hand in hand in other organs and there may be an advanced interstitial pancreatitis with only a small amount of hemosiderin The spleen nearly always shows some fibrosis as do the heart, thyroid and salivary glands The fibrosis, both in the liver and pancreas, has usually been considered the *result* of irritation produced by the iron pigment Sheldon, however, concluded that the two processes, namely hemosiderosis and fibrosis, are independent of each other Herbut and Tamaki²¹ agree with this view and emphasize the fact that fibrosis occurs almost exclusively in the liver, pancreas and spleen, and is not found in other organs in spite of the fact that hemosiderosis may be very severe in them They believe that the excess of fibrous tissue in both pancreas and spleen is due to portal hypertension Degenerative changes in the parenchymatous cells do not occupy a prominent place apart from the direct mechanical damage to the cells by the surrounding fibrous tissue Even where there is no pigment it is common to see collections of degenerated cells surrounded by thick rings of fibrous tissue

Chemical investigation reveals a great increase of iron in the various organs which may be 50 to 100 times normal in the liver, pancreas and salivary glands The total amount of iron in the body has been estimated at from 20 to 58 grams, of which as much as 38 grams has been found in the liver Spectrographic studies have revealed an increase of calcium in the tissues paralleling the increase in iron, ex-

ceptions being the lung, trachea and urinary bladder, which have less calcium than the control tissues, but have a marked increase of potassium. An increase of copper has been noted in most tissues,³⁹ exceptions being the suprarenals and jejunum which have normal values, and the kidney which has less than normal.

Relation of Hemochromatosis to Various Etiologic Factors

Soper⁴⁴ reported a typical case of hemochromatosis in a metal worker who was in contact with large amounts of copper, lead and zinc. Creed¹⁰ had a man who drank wine from a barrel lined with copper, while Gray¹⁸ described the case of a copper miner. Lawrence²⁹ reported on the familial incidence of the disease in a family of nine siblings. Of the 4 males, 2 had typical hemochromatosis, a third had a borderline case, while the fourth was unaffected. Vitamin A deficiency with defective intestinal mucosa has also been postulated as possibly responsible.⁴⁶

Iron metabolism in hemochromatosis Although studies made by Keilin²⁶ in 1926 on the tissues of a case of hemochromatosis did not reveal any obvious disturbance in the intracellular metabolism of iron, it is felt that the iron cytochrome is undoubtedly subject to replacement in health as a result of the normal wear and tear of the tissues, and may be left in a form which the cells are unable to excrete when due for replacement. This would also account for the increased copper, since Elvehjem¹² has shown that copper is necessary for the formation of cytochrome. In normal individuals, iron is taken in the diet in amounts of from 8 to 10 milligrams daily, partially absorbed in the duodenum, and excreted in minimal amounts through the large bowel and the kidneys. Iron is stored in the liver and only a slight trace is excreted in the bile. The body normally contains less than 5 grams of iron, more than half of which is in the hemoglobin. In hemochromatosis, the body excretes some iron in the stools, but none in the urine or bile. The iron accumulates in the body,¹ as much as 58 grams having been reported.

The dietary intake of the average individual would provide enough iron for normal blood formation with an excess of from 25 to 50 grams by the age of 45 or 50 if the disease were congenital. If this were so, one might even expect to find cases with a familial incidence. Such have indeed been reported,²⁹ but for some reason have attracted little attention.

Howard and Stevens,²² McClure,³⁴ Fowler and Barer,¹⁴ and Dry¹¹ have all shown that iron absorption is no greater in hemochromatosis than in normal patients. Fowler and Barer however, had an early case which did demonstrate increased absorption over a short period of study. Marble and Smith, in 1939,³³ gave iron to a patient with hemochromatosis for a twelve day period. Absorption was 1.8 milligrams per day, the same as in a normal control. Sachs, Levine and Griffith⁴¹ showed the average normal whole blood iron to be 50 micrograms, and copper to be 0.132 micrograms per 100 cc. In their 3 cases of hemochromatosis the values for whole blood iron ran from 37 to 44 micrograms and copper from 0.130 to 0.156 micrograms. They thought that the low iron values were due either to the slight anemias which were found in all 3 cases or that the increase in the deposition of iron in the tissues tended to reduce the quantity of circulating iron.

Experimental Hemochromatosis Muir and Dunn, in 1915,³⁶ produced a rapid he-

molysis in rabbits by injecting an immune body intravenously. They demonstrated that most of the iron resulting from destruction of the red cells was deposited in the liver, spleen, and kidney on the fourth and fifth days. After the ninth day these organs contained little over the normal amount of iron. Rous and Oliver, in 1918,¹¹ injected rabbits with rabbit blood for several months without producing hemochromatosis. They did, however, demonstrate hemosiderin deposits in the liver. Mallory, in 1921,³² gave rabbits copper acetate for as long as eleven and a half months. He produced pigmentation, similar to hemofuscin, and cirrhosis in three rabbits. He believed that hemofuscin is changed to hemosiderin in some way and, after saturating the liver, is deposited in the pancreas, adrenal, thyroid, spleen, heart, skin and stomach. Polson, in 1929,³⁷ gave rabbits dialyzed iron intravenously for three months and then sacrificed them one week to fourteen months later. He demonstrated that the iron moved from the lungs to the liver via the spleen. No evidence of cirrhosis or hemochromatosis was noted in the liver. Cappell, in 1930,⁷ gave colloidal iron to rabbits and showed that the iron was taken up by the reticulo-endothelial system, later entered into loose combination with plasma protein and passed into the liver, kidney and spleen, there was none in the pancreas. Taylor, Stiven and Reid, in 1931,⁴⁶ induced hemochromatosis by depancreatizing a cat, and giving it a poorly balanced diet. This was the first recorded experimentally produced hemochromatosis. Polson³⁸ later extended his original experiment and gave iron subcutaneously and intraperitoneally for periods ranging from one to four years. Hemosiderin was deposited in the tissues, but no cirrhosis or hemochromatosis were produced. Menkin in 1934³⁵ gave intravenous injections of ferric chloride to rabbits for a number of weeks and produced hemosiderosis, showing that hemosiderin is not solely a product in the degradation of the hemoglobin but may result from a release of iron in the body fluids. In 1946, Herbut, Watson, and Perkins²⁰ showed that in 2 of their 30 rabbits with alloxan diabetes there was an associated cirrhosis of the liver, and to a lesser extent of the pancreas. Here, for the first time, two of the three important manifestations of hemochromatosis were noted, produced experimentally in animals by a single agent. The third manifestation, namely hemosiderosis, was produced by feeding reduced iron to the surviving diabetic rabbits.

Relationship of Hemochromatosis to Metabolic Diseases

In 1945, Gillman, Mandelstam and Gillman¹⁵ pointed out the relationship of hemochromatosis to nutritional disturbances in pellagrins. Their study was based upon histologic examination of 500 liver biopsies in South African natives. They emphasize in subsequent studies¹⁶ that the excess of iron in the liver cell in cytosiderosis (hemochromatosis) can arise in only a limited number of ways, namely by the increased mobilization of iron from the red corpuscles and other bodily stores, by increased absorption and diminished excretion, and by abnormal utilization with normal absorption. Excessive destruction of the red blood cells has long been regarded as a potential cause of cytosiderosis of the liver. In pernicious anemia and the hemolytic anemias,⁴⁵ there is hemosiderosis but no cirrhosis. In malaria,

the liver and Kupffer cells are loaded with iron pigment but cirrhosis is absent.⁵ In attempted experimental hemochromatosis, by the parenteral administration of colloidal iron to animals, the reticulo-endothelial system first becomes heavily laden with this metal, and only after a period of days or even months do the liver cells begin to accumulate iron. From this it may be concluded that the iron first accumulates in the Kupffer cells and only later does it appear to any extent in the liver cells. It has been suggested that cytosiderosis is in all probability due to a disturbed intracellular metabolism affecting the mitochondria, induced in some inexplicable way by a poor diet. Kremer²⁸ has shown an increase in the iron pigment in the liver of hibernating and starving frogs. Gore,¹⁷ in 1939, reported the occurrence of pellagra and hemochromatosis. Taylor, Stiven and Reid⁴⁶ produced cytosiderosis in the cat by a badly balanced diet, and the Gillmans¹⁶ have further focused attention on this relationship.

In reviewing 115 autopsied cases of cirrhosis of the liver, Herbut and Tamaki²¹ found that 12 had diabetes mellitus. They brought out the fact that various combinations of cirrhosis of the liver, pigmentation, fibrosis of the pancreas, and diabetes mellitus do occur, and that the gradations from one to the other are so subtle that it is often difficult to know exactly when to apply the term hemochromatosis.

The deposits of hemofuscin are explained as part of a general disturbance of the metabolism of melanin, a pigment similar to hemofuscin. The hemosiderosis of the adrenals may in some way be related to this. The cause is probably ultimately referable to the abnormal metabolism in the parenchymatous cells and it is probably for this reason that sclerosis of some degree develops in so many of the organs and seems to vary in intensity with their levels of metabolism.

Association of Hemochromatosis with Multiple Blood Transfusions

The first case of hemochromatosis associated with multiple blood transfusions was reported by Kark in 1937.²⁵ This occurred in a 39 year old male who had received over 290 transfusions during a period of nine years. Bomford and Rhoads²³ reported 3 cases of a series of approximately 60 patients who had "refractory anemias." They were as follows: a 51 year old male who received 13 transfusions in one year, a 38 year old male who received 12 transfusions in sixteen months, and an 18 year old male who received 38 transfusions in five years. MacKey³¹ reported a case of hemochromatosis in a 50 year old male who had received 39 transfusions in three and one-half years. Zeltmacher and Bevans⁴⁸ reported a 65 year old male who received 12.8 liters in one year. Humphreys and Southworth²³ reported a 58 year old female who had 52 transfusions in twenty-two months. Chesner⁸ reported a 14 year old boy who had 12 transfusions over a period of nine months. The present report adds 5 cases: a 47 year old Negro female who had 75 transfusions in a period of four and one-half years, a 37 year old white female who had 65 transfusions in nine months, a 19 year old white female who had 21 transfusions in nine months, a 73 year old white female who had 23 transfusions in two years, and a 49 year old white female who had 58 transfusions in two years, bringing the total number of reported cases to 13.

DISCUSSION

Hemochromatosis is a metabolic disease characterized primarily by an abnormally great retention and deposition of iron throughout the body. The iron is deposited in the form of hemosiderin. It has the greatest affinity for gland cells but nearly all tissues are ultimately affected. Two explanations, neither mutually exclusive, might explain the mechanics of the disturbed pigment metabolism according to Sheldon. Thus, "both pigments (hemosiderin and hemofuscin) might be the result of a disturbance of the normal changes in intracellular chemistry which are dependent on the process of ageing of the cell, or the hemosiderin might be due to an anomaly in the metabolism of the intracellular respiratory pigments whereby, though themselves of normal structure, the iron involved in their wear and tear is able to enter the cell without hindrance in either normal or increased quantity but becomes so altered while in the cell that it cannot be excreted, and consequently accumulates until the cell is distended to bursting point." Regardless of the pathogenesis of endogenous hemochromatosis, it is evident from animal experiments that the administration of iron parenterally results in its deposition in excess quantities, first in the reticulo-endothelial system and later in the parenchymal cells. Though this is sequentially the reverse of what supposedly happens in endogenous hemochromatosis the end results appear to be indistinguishable. Once extensive hemosiderosis occurs, the remainder of the picture develops as a consequence of the irritation of the foreign substance, and whereas the hemosiderosis in itself is apparently innocuous, the secondary fibrosis it produces is ultimately fatal. Fibrosis of the pancreas and the resultant diabetes with its complications account for about 50 per cent of the deaths while the fibrosis of the liver accounts for about 18 per cent (due to hematemeses, hepatic failure, and liver carcinoma).

It is not the purpose of this paper to evaluate the etiologic theories of endogenous hemochromatosis. Suffice it to say that the question relating to the ultimate cause of the iron retention has so far remained unanswered. It seems to us that the only *ultimate* cause can be *increased absorption of iron from the gastrointestinal tract*. Whether this absorption in turn is dependent upon an increased permeability of the cells of the gut, or an increased absorptiveness due to a low serum iron, as the work of Sachs, Levine and Griffith⁴¹ would indicate, cannot be concluded from presently available evidence. Nor is it as yet clear, should this finding be substantiated, whether this is a primary defect or secondary to an increased 'avidity' of the parenchymal cells for iron. It is certain, however, that simple blood destruction cannot explain hemochromatosis either theoretically or on the basis of clinical or experimental evidence, since it is known that conditions characterized by increased blood destruction and hemosiderosis (such as hemolytic anemias, malaria, pernicious anemia, etc.) are not accompanied by fibrosis.

If we postulate, as indeed we must, that an increased amount of iron is present before hemochromatosis can occur, then, theoretically at least, any overloading of the organism with iron should result, at first in hemosiderosis, and ultimately hemochromatosis. The animal experiments referred to above bear out this hypothesis and probably failed to produce the complete picture because of insufficient insult and/or inadequate time.

Considering the rarity of hemochromatosis, the development of this disease in anemic patients who have had multiple transfusions appears to be more than simple coincidence. It is possible that the disturbed intracellular metabolism resulting from the anoxia due to the anemia may be contributory, making proper disposal of the iron pigment impossible. Thus, there would be an accumulation of hemosiderin, with eventual fibrosis added to the previously deranged cellular metabolism.

Theoretically, hemosiderosis should be producible in many ways and by any means which will increase the iron in the body over physiologic storage levels. This should be more readily accomplishable in the male whose iron excretion is much more limited than that of the female. Perhaps this is one of the explanations for the remarkable disparity between the incidence of hemochromatosis in the two sexes. The female has the opportunity, by pregnancies and menstruation, to lose quantities of blood which would tend to keep the accumulation of iron down to a point where, at least until the menopause, the hemosiderosis would be retarded. The age incidence of the disease, too, fits this concept, since to develop the full blown disease at the age of 50 (assuming the condition to be congenital) there would have to be an average daily excess positive iron balance of from only 1 to 2.5 milligrams.

Many more transfusions would have to be given, to administer enough iron to compare quantitatively with the amounts demonstrated in hemochromatosis, than the numbers either in our own cases or those previously reported, since a transfusion of 500 cc of blood contains approximately only 250 milligrams of iron. A satisfactory explanation for the recovery of 45 grams of iron in the liver in Chesner's case,⁸ after having received a total of 6 liters of blood or 2.75 Gm of iron, on the basis of retention of transfused iron is still difficult to answer. We must, therefore, search for other factors which might be operative. Poor nutrition has been incriminated both clinically and experimentally, but we have no evidence of this in the present series. The only common denominator of our and other reported cases is anemia, regardless of type, for which the transfusions were given. As has been mentioned before, it is not inconceivable that the anoxia due to the anemia plays a contributing role by disturbing the intracellular metabolism, and thereby making the cell more susceptible to the deposition of iron. Significant additional amounts of iron are made available to these patients by oral administration which is universally done in the attempt to combat the anemia.

That the cases under discussion differ from the classic 'idiopathic' hemochromatosis is indisputable. It is, however, worthy of note that there are enough of the prime features in common to suggest that these cases represent intermediate or early forms which in time would probably show more and more of the classic features of the disease, since the typical case differs only in degree and extensiveness. Whereas classic hemochromatosis is characterized by fibrosis of the liver, pigmentation of the skin, diabetes mellitus, and sexual hypoplasia, of the cases reviewed here only 2 had clinically demonstrable diabetes and only 5 had skin changes worthy of note. There was no significant sexual hypoplasia in any of the cases. However, in 9 of the 13 cases there was a significant enlargement of the liver, and in all 12 of the 13 cases in which either autopsy or liver biopsy were obtained a

TABLE 1—Cases of Exogenous Hemochromatosis

Author and Date	No of case	Sex and Age	Primary Diagnosis	Duration	Number of Transfusions	Initial Blood Count	Last Blood Count	Marrow Findings	Skin	Liver	Spleen	Diabetes
R M Kark 1937	1	39 male	Aplastic Anemia	9 years	290 (plus)	Hgb 50% RBC 2 50 WBC 3,500	Hgb 50 to 70%	Many red cells present but normal hematopoietic tissue somewhat deficient Eosinophils and round cells plentiful Extreme replacement of marrow with fat	Peculiar slate gray color Pigmentation of conjunctivae and teeth	Enlarged down to umbilicus	Not enlarged	Fasting blood sugar 150 mgs /100 c cm
R R Bonford and C P Rhoads 1941	2	51 male	Aplastic Anemia	16 months	15	Hgb 30% RBC 1 40 WBC 1,150	RBC 1 00	Slightly hypocellular with isolated areas of active hemopoiesis No megakaryocytes	Blackish brown pigmentation of hands and arms	1,500 Gms	Not enlarged	
	3	68 male	Pseudo Aplastic Anemia		12	RBC 1 50	RBC varied from 1 0 to 2 00 WBC 2,000 to 5,000	Hypercellular Reduced number of megakaryocytes	Severe jaundice Brown pigmentation of skin	1 840 Gms	130 Gms	
	4	21 male	No Diagnosis	8 years	55	Hgb 26% RBC 1 30 WBC 3,850	Hgb 30% RBC 1 40	A partly mature marrow with few megakaryocytes	Brown pigmentation	Not enlarged	Slightly enlarged	Present
R Mackay 1942	5	46 male	Aplastic Anemia	3½ years	39 8 liters	Hgb 22% RBC 1 05 WBC 4,100	RBC varied between 1 10 to 2 70	Increased in amount Deep brown color Increased granulocytes in all stages Increased lymphocytes Normal megakaryocytes Only occasional nucleated red blood cell		2,400 Gms	450 Gms	

K /elt marker and M Devans 1915	6	65 male	Pseudo Aplastic Anemia	1 year	12.8 liters	Hgb 36% RBC 1.40 WBC 4,900	Varied from RBC 1.15 to 2.50 Hgb 34% to 54% WBC 2,600 to 6,100	Very cellular with RBC WBC ratio 1:1 Marked shift to left in nucleated RBC and dimin- ished numbers of mature granulo- cytes	Gray-brown	3,050 Gms	250 Gms	Tasting blood sugar 110 and 130
G. H. Hum- phreys and H. South- worth 1915	7	58 female	Aplastic Anemia	3 years	52	Hgb 10% RBC 1.00 WBC 10,000	Hgb 95% RBC 4.00	Mild hypoplasia of marrow but no ab- normal cells	Normal	6 cm below costal mar- gin	Not palpable	None
C. Chesner 1916	8	11 male	"Banti's Dis- ease"	7 1/2 months	6 liters	Hgb 3.9 Gm RBC 2.50 WBC 4,000	Hgb 6 Gm RBC 2.50 WBC 3,000	Hyperplasia of the erythroid ele- ments	Pale	2,350 Gms	3 fingers down from costal margin	
S. O. Schwartz and S. A. Blumen- thal 1917	9	19 female M. P.	Congenital hypoplasia of kidneys with chronic glomerulo- nephritis	9 months	21	Hgb 44% RBC 2.24 WBC 6,500	Hgb 50% RBC 3.01 WBC 6,000	Relatively acellular, made up mostly of granulocytic cells with right shift	Scaly maculo- papular eruption	5 cm below the costal margin 1,665 Gms	Not enlarged 165 Gms	None
	10	73 female R. H.	Aplastic Anemia	2 years	23	Hgb 50% RBC 1.72 WBC 9,000	Hgb 19% RBC 1.12 WBC 6,900	Hypoplastic mar- row	Pale	900 Gms	50 Gms	None
	11	49 female C. K.	Anemia with hepato- spleno- megaly	2 years	58	Hgb 36% RBC 2.50	Hgb 9% RBC 1.30 WBC 14,100	Hyperplastic mar- row with moderate replacement by large primitive cells which may represent eryth- roid elements	Dark color	1,980 Gms	520 Gms	Present

Author and Date	No of case	Sex and Age	Primary Diagnosis	Duration	Number of Transfusions	Initial Blood Count	Last Blood Count	Marrow Findings	Skin	Liver	Spleen	Diabetes
	12	37 female J B	Aplastic Anemia	9 months	65	Hgb 44% RBC 2.34	Hgb 22% RBC 1.09	Hypocellular marrow with small islands of normal erythropoiesis	Pale	Not enlarged	Not palpable	None
	13	47 Negro female V G	Anemia with hepato spleno megalia	4½ years	75	Hgb 12% RBC 0.70 WBC 9,300	Hgb 60% RBC 3.76 WBC 25,600	Hypercellular marrow Megakaryocytes normal Remarkable increase in primitive red cells No megaloblasts noted Shift in granulopoiesis, with numerous giant band forms and metamyelocytes Increased number of cosinophils	Dark	8 cm below the costal margin 3,160 Gms	4 cm below the costal margin 780 Gms	None

CASE 1 *Autopsy* Autopsy refused *Skin biopsy* Brown, iron containing pigment in secretory cells of the sweat glands, lesser amount in the sebaceous glands and diffuse distribution in the connective tissue and basement membrane *Remarks* Patient began to develop the peculiar skin changes of hemochromatosis and enlarged liver about 8 years after the beginning of the transfusion series

CASE 2 *Autopsy* Hemosiderosis and fibrosis of liver, pancreas and lymph nodes *Remarks* Immature hypoplastic marrow Liver firm, golden brown cut surface, pancreas deep brown in color Considerable hemosiderosis and multilobar fibrosis of liver and pancreas *Remarks* Prior to transfusions patient was treated unsuccessfully with iron, liver copper and vitamins

CASE 3 *Autopsy* Broncho pneumonia of right lower lobe Spleen brownish purple cut surface, liver abundant golden brown pigment around portal areas Pancreas deep brown in color Considerable hemosiderosis and multilobar fibrosis of liver and pancreas *Remarks* History of severe nosebleeds from age of 5 to 7, bleeding tendencies and purpura with splenectomy at age of 13

CASE 4 *Autopsy* Typical findings of hemochromatosis with hemosiderosis and fibrosis of liver and pancreas *Remarks* Periportal fibrosis and free iron demonstrated in reticulo-endothelial cells and parenchymal cells Evidences of hemochromatosis noted in pancreas lymph nodes and heart *Remarks* Previous history was negative

CASE 5 *Autopsy* Liver orange brown loaded with hemosiderosis Spleen had a small amount of iron pigment Pancreas was heavily pigmented and fibrotic Prostate, lymph nodes, adrenal thyroid and heart contained pigment Marrow showed evidence of regression toward a more immature state Lungs emphysematous Right heart enlargement

CASE 6 *Autopsy* Iron staining pigment in liver pancreas bone marrow thyroid adrenals spleen and lymph nodes *Remarks* This patient had a profound depression of erythrocyte formation for many years and had to be maintained on blood transfusions following removal of a mediastinal tumor her red count went back to normal and she remained well for one year when she developed an abscess in her thigh followed by acute ascites jaundice and death

hemosiderosis and fibrosis of the liver were found. Of equal importance was the finding of both hemosiderosis and fibrosis in all 11 cases where pancreatic tissue was examined. In the thirteenth case, only a skin biopsy was obtained.

It seems important to recognize that in dealing with simple hemosiderosis, exogenous hemochromatosis with secondary fibrosis, and hemochromatosis of the idiopathic type we are dealing with varying gradations of the same aberration. From observations made in our own cases, together with the findings of previous investigators (both clinical and experimental), it may be concluded that the deposition of excess amounts of iron will lead to irritation, fibrosis and ultimately to destruction. Whether this is precisely the sequence of events that occurs in hemochromatosis is unknown and seems to be somewhat controversial. It is not unlikely that other factors besides the simple deposition of iron may be responsible for the fibrosis. We are, of course, dealing here with a highly selected group of cases, all of whom had a profound anemia which undoubtedly damaged the liver parenchyma as well as the parenchyma of other organs, especially those with high metabolic needs. It is important in this connection to re-emphasize the fact that the organs most involved in hemochromatosis are those with high metabolic levels and oxygen consumption. The factor of hemolytic transfusion reactions, not by virtue of hemolysis but because of the accompanying fever and further parenchymatous tissue damage, may well have been an aggravating circumstance. Although this was not of universal occurrence its importance cannot be minimized.

One of the striking differences between the cases here reviewed and those of typical hemochromatosis is the marked difference in the ratio of males to females. In endogenous hemochromatosis, the ratio is about 20 to 1 in favor of males. In the present series, there are 7 males and 6 females, while in our own series all 5 were females. Of further interest is the fact that, whereas the classic picture is practically unknown before the age of 20, there were 3 cases in the present group between 14 and 21 years of age.

Fully developed hemochromatosis, showing all the manifestations of the disease, will undoubtedly be encountered in time because of the increasing utilization of blood transfusions and the greater longevity of patients having hematologic dyscrasias. There seems to be a definite relationship between the degree of hemosiderosis and fibrosis and the factors of time and number of transfusions. By and large, the patients receiving only relatively few transfusions or transfusions over a relatively short period of time seem to show the least involvement, whereas patients who receive many transfusions over long periods of time (cases 1, 4, 5, 11 and 13, table 1) will have the greatest amount of involvement. It is obvious from the foregoing discussion that patients to whom blood is given for the purpose of replacing lost blood will have no tendency to develop hemochromatosis since the iron is simply being replaced as it is lost from the body.

Our own interpretation of endogenous hemochromatosis is that it is a metabolic disease in which excess amounts of iron are absorbed from the gastrointestinal tract. Whether this excess iron is absorbed due to the fact that there is a breakdown of the barrier in the gut or whether there is an abnormally low serum iron, either as a distinct abnormality or due to the avidity of various tissues for iron, we are

is yet unprepared to say. In those cases where iron is introduced into the body parenterally either in a free or combined state (as in the form of red cells which are eventually broken down to hemoglobin) and becomes stored, it is gradually laid down in the various storage depots because no mechanism of excretion exists. When the storage depots become overfilled the parenchymatous cells, which under normal circumstances do not contain iron, will take up the excess. We believe that this same sequence of events occurs in endogenous hemochromatosis and hence the greater incidence in males and the reason for the occurrence of the disease in later life.

It is worthy of note that the underlying disease for which the transfusions are given is not of prime importance. Diagnoses included true aplastic anemia, pseudo-aplastic anemia, chronic uremia, and others. In this connection it is particularly noteworthy that there is never a significant anemia in the classic hemochromatosis. Therefore, the assumption that these cases had hemochromatosis and were complicated by anemia, for which in turn the transfusions were given, is fallacious.

The therapeutic suggestion of venesections and iron deficient diet presents itself in the management of hemochromatosis. It is not thought that this regime will be curative, but may serve, by reducing the hemosiderin deposits, as an ameliorating factor in the course of the disease.

CASE REPORTS

Case 1 Marilyn P.

Patient was a 19 year old white female who entered the hospital with a history of weakness, dyspnea, headaches, anorexia, sore throat and sore tongue, generalized pruritic scaly dermatitis, and recurrent bouts of epistaxis for a year. Past history revealed that she had scarlet fever during childhood and frequent sore throats subsequently. During the year preceding admission she had been treated with iron for anemia. On examination she was found to be poorly developed, but well nourished. The skin was covered by a pale, tan, finely scaly, maculopapular eruption involving the trunk and extremities. Blood pressure was 120/60. The temperature was normal. Transitory attacks of twitching and convulsions with mental aberrations were noted. Significant laboratory findings on admission were Hgb, 44 per cent, RBC, 2.24, WBC, 6,500, polys, 82 (bands 1), eosinophils, 1, lymphocytes, 10, monocytes, 7. The red cells showed slight anisocytosis and poikilocytosis, the granulocytes, slight toxicity. Urinalysis albuminuria 2 plus, with 15-20 WBC and occasional RBC per HPF. NPN, 304 mg per 100 cc, creatinine, 16.7 mg per 100 cc, total proteins, 7.2 Gm per 100 cc, serum calcium, 5.6 mg per 100 cc, inorganic phosphorus, 11.2 mg per 100 cc. Marrow was relatively acellular and consisted mostly of granulocytes which showed a right shift. She was given Blaud's pills, multiple vitamins, intravenous fluids, and sodium and calcium therapy.

During the next several months she was in the hospital on three other occasions. During these, 18 transfusions of 500 cc blood were given. The final admission was eight and one half months after the first because of an exacerbation of the uremic symptoms of weakness, nausea, anorexia, skin rash and epistaxes. The blood pressure had risen to 172/126. There were rales at both lung bases, an ascites, a palpable, tender liver 4 cm below the costal margin, and ankle edema. The urine now had 4 plus albumin. Hgb, 50 per cent, RBC, 3.01, WBC, 6,000, polys, 83 (bands 13), eosinophils, 1, lymphocytes, 12, monocytes, 4. NPN, 161 mg per 100 cc, creatinine, 14.8 mg per 100 cc, calcium, 7.5 mg per 100 cc. She gradually became more stuporous and died in uremic coma nine months after first entering the hospital. Three additional transfusions of blood were given during this admission.

On postmortem examination, bilateral hypoplastic kidneys were found. These showed a chronic recurrent glomerulonephritis which was chiefly intracapillary. There was also hypoplasia of the renal arteries and the aorta. In the liver (1,665 Gm), there was marked hemosiderosis with reactive periportal

fibrosis and bile duct proliferation. The spleen (165 Gm) showed a chronic reactive hyperplasia with hemosiderosis. There were also hemosiderosis of the lungs and lymph nodes and a slight interstitial

FIG. 1. Slight interstitial pancreatitis and increase in fibrous tissue (H and E Stain) Case 1 160 X

FIG. 2. Liver, showing slight increase in connective tissue (Mallory stain) Case 1 160 X

pancreatitis. Other findings were the marked hypertrophy and dilatation of the heart, bilateral hydrothorax, ascites, anasarca, uremic pericarditis, beginning uremic colitis, and hemorrhagic infarct of the lower lobe of the right lung.

Comment This 19 year old girl had a severe anemia secondary to chronic uremia. During the nine month observation period, she received 21 transfusions of 500 cc blood in addition to ferrotherapy. Her liver, lungs, lymph nodes and spleen showed hemosiderosis. The liver, however, already had some periportal fibrosis at the time of death. It is difficult to say whether the pancreatitis was part of the picture. There were no skin changes or diabetes in this case. It is of great interest that periportal fibrosis should be demonstrable as early as nine months after the start of transfusions. There is nothing in the underlying disease which in itself should have predisposed this patient to liver damage or fibrosis other than the anemia and the hemosiderosis.

Case - Ret a II

Patient was a 73 year old white female whose main complaints were weakness for five months, fatigue, and pins and needles sensations in the fingertips for four weeks. Some dyspnea on exertion, coldness of the feet, belching after meals, a dry tongue, and an 11 pound weight loss had also been noted. Past history was noncontributory. On examination she was found to be well developed and well nourished, pale, and with a yellowish tint of the skin. The tongue was coated. There was a loud, rough, systolic murmur heard at the apex, which was transmitted to the neck and axilla. The blood pressure was 135/70. There was some tenderness in the left upper quadrant. Liver was felt 1 centimeter below the costal margin. Large varicosities were noted in the lower extremities. There was an ankylosis of the left hand on an orthopedic basis. Significant laboratory data were: negative urines, stools and serologic findings. Gastric analysis after subcutaneous histamine: free acid, 29°, total acid, 50°. Normal BMR and EKG. NPN, 29 mg per 100 cc, blood sugar, 77 mg per 100 cc, cholesterol, 118 mg per 100 cc, cholesterol esters, 70 per cent. X rays: Gallbladder showed good dye concentration and the roentgenologic examination of the gastrointestinal tract was negative. Blood count on admission was as follows: Hgb, 50 per cent, RBC, 1,72, WBC, 9,000, polys, 56, eosinophils, 2, lymphs, 34, monocytes, 8, anisocytosis, 2 plus, microcytosis, 4 plus. Platelets, 110,000, fragility test, normal. Marrow: hypocellular, with marked diminution of both erythropoiesis and granulopoiesis and increase in lymphoid elements. She received liver extract and one blood transfusion without benefit during her four week hospital stay.

She was rehospitalized nine months later and on this admission it was learned that she had been taking phenobarbital every night for the preceding eight months, and on and off for the previous six years. Her symptoms were the same as before but her arthritic pains had increased and a rash had appeared over the back and shoulders. She was again extensively studied, received two transfusions and was sent home after four weeks. There were four other admissions, the last one twenty-three months after the first. This admission was because of a pneumonia and pyelonephritis. Five blood transfusions were given during this admission, but despite these and other supportive measures she progressively failed and died two and one half months later. She had received a total of 23 blood transfusions during the two years of observation.

On postmortem examination the following pertinent findings were noted: hypoplasia of bone marrow, hemochromatosis of liver, spleen and pancreas, icterus with purpura, left pyelonephritis with cortical abscesses, moderate coronary artery arteriosclerosis with myocardial fibrosis, healed endocarditis of tricuspid, mitral and aortic valves, old pleuritic adhesions (rt) with *Durchwandrung* perihepatic adhesions.

Comment This 73 year old patient was studied over a two year period, during which time she received 23 blood transfusions. Many of the transfusions were followed by severe febrile and hemolytic reactions, which, in retrospect, were probably due to the then unknown Rh factor. What aggravating role these reactions played it is impossible to say, but they may have produced enough liver damage to have at least contributed to the ultimate fibrosis of the liver and other organs. It is

not thought significant that the blood was rapidly destroyed during these reactions rather than in the normal way. There is no evidence to indicate that the underlying

FIG. 3. PANCREATIC FIBROSIS (H AND E STAIN) CASE 2. 320 X

FIG. 4. Increased pigment in liver cells (Basic fuchsin and nitric acid stain) Case 2. 320 X

aplastic anemia was in any direct way related to the hemochromatosis. This patient had no clinical evidence of diabetes or skin involvement.

Figure 1. Pericardial tissue with increased connective tissue and infiltration with round cells. Hemosiderin pigment deposits are interstitial. H and E stain. Case 160.

Case 160 (Cont.)
 Patient was a 49-year-old white female who entered the hospital with a history of weakness, palpitation, dyspnea, nervousness, anorexia and a 30 pound weight loss in the previous two years. During the

four months before her present hospital admission she had received 11 transfusions for anemia at a private hospital. Except for a right sided oophorectomy in 1927, her previous history and family history were noncontributory. She took milk of magnesia quite frequently and occasionally aspirin for headaches. She was found to be well developed and well nourished. The skin was pale and had a slightly icteric hue. There were a few small discrete submaxillary lymph nodes, a marble sized node in the left axilla, and a few palpable nodes in the inguinal region. The heart was enlarged to the left. A soft systolic murmur was heard at the apex and there was a systolic murmur at the base. The liver was moderately hard and could be felt 3 cm. below the costal margin. The spleen was felt 2 cm. below the costal margin.

Laboratory findings of interest were the following: Hgb, 36 per cent (5.6 Gm.), RBC, 2,500,000, WBC, 7,900, polys, 59, lymphs, 27, monocytes, 13, eosinophils, 1. Platelets, 170,000. Urines, blood serology and stools negative. Serum protein, 7.4 Gm., inorganic phosphorus, 4.7 mg., acid phosphatase, 0. Icterus index, 9. EKG slightly abnormal, with left axis deviation. Sternal marrow revealed an extraordinary cellularity, the megakaryocytes were normal, granulopoiesis was intact, erythropoiesis was accelerated to a remarkable degree and showed a marked left shift with very primitive erythropoiesis predominating. X-rays of the bones and the gastrointestinal tract were negative. The chest x-ray showed a boot shaped heart and accentuated hilar markings bilaterally, but otherwise lung fields were normal.

She was given 6 blood transfusions during a period of eighteen days, and was discharged, significantly improved both clinically and hematologically. No satisfactory diagnosis was established.

She was readmitted six months later because of a recurrence of weakness. There were no significant changes in her physical findings. The blood findings now were: Hgb, 36 per cent (5.6 Gm.), RBC, 2,710,000, WBC, 10,400, polys, 49 (bands 37), myelocytes, 2, metamyelocytes, 10, eosinophils, 1, basophils, 1, irritation cell, 1, lymphocytes, 18, monocytes 18. This time she received 8 blood transfusions during a three week period.

Two months later she was admitted to another hospital. Her liver now was 9 cm. and the spleen 6 cm. below the costal margin. Hgb, 23 per cent (3.6 Gm.), RBC, 1,400,000, WBC, 6,300, polys, 63 (bands 45), lymphs, 9, monocytes, 6, basophils, 1, myelocytes, 10, metamyelocytes, 11. BMR was +40. Otherwise, nothing new was found. Despite a total of 20 blood transfusions during this four month hospitalization her blood count still remained quite low.

Thirteen months after her first hospitalization she entered still another hospital. Here she received 13 more blood transfusions and splenectomy was performed. Her postoperative course was stormy, she developed pleural effusions and an hemopericardium, and died about six weeks later. Most significant single contribution clinically during this hospitalization was the discovery of a mild diabetes.

Postmortem examination revealed a pigment cirrhosis of the liver, hemosiderosis of the liver, stomach, adrenal glands, and lymph nodes. There was an interstitial fibrosis of the pancreas with extraordinarily large amounts of hemosiderin deposits involving especially the islands of Langerhans. The marrow was hyperplastic and the extirpated spleen showed myeloid metaplasia. Other findings were a fatty degeneration of heart and kidneys, subacute fibrinous pericarditis, chronic abscess of left upper quadrant of the abdomen, left pleural effusion, and septicemia (*staphylococcus aureus*).

Comment This 49 year old woman was studied at four institutions during her two years of illness. Every conceivable diagnosis was made and all types of therapies used in hematology were tried without success. Even postmortem examination failed to explain the cause of her anemia, or cast light upon the type of maturation failure seen in the primitive erythrocytes.⁴²

During the two years of study she received 58 transfusions of blood, most of them uneventfully. Of greatest interest in this patient was the recognition of early diabetes some time before her death, explained pathologically by the large amounts of hemosiderin deposits in the islands of Langerhans and by the fibrosis in the pancreas. She had extensive hemosiderin deposition in most organs and, significantly, cirrhosis of the liver. This patient's skin was quite dark, having become more so during her last few months. Unfortunately no skin biopsy was obtained—one of

the disadvantages of retrospective investigation. It may also be said in retrospect that the splenectomy was not justified since the enlargement of the spleen was apparently secondary (due to compensatory extramedullary hemopoiesis) rather than the cause of the anemia. (This case has been previously published ³⁰)

Case 4 Jean B

Patient was a 37 year old white female who entered the hospital because of malaise, fatigability, dyspnea, ankle edema and palpitation for one month. She was actively bleeding vaginally on admission and had just been discharged from another hospital where one blood transfusion was given. For twenty-three years she had had menorrhagia lasting from one to four weeks, associated with dysmenorrhea for which she frequently took Anacin and Midol. There had also been many nose bleeds during the

FIG 7 Periportal area showing increased hemosiderin pigment deposition (H and E stain) case 4 160 X

last several months. The patient worked in a pie factory most of her adult life. She had had an appendectomy and had never been pregnant, denied having had syphilis or having received anti-leukemic therapy. She was well developed and well nourished, and appeared pale and weak. The hair was dried. The pupils were equal but asymmetrical and did not react to light or accommodation. There was a loud, blowing systolic murmur heard at the apex and base of the heart. Neither the liver nor the spleen were palpable. The extremities were covered by numerous large ecchymotic areas. A lemon sized cystic mass was palpated in the left adnexa, and the uterus was in the cul-de-sac.

Only laboratory findings of significance were the negative serologic tests for syphilis, the hematologic findings, and the marrows. The blood revealed Hgb, 44 per cent (6.8 Gm), RBC 2.34, WBC 2,150 polys, 65 (bands 25), lymphocytes, 27, monocytes, 8. Platelets, 7,000 (two days after blood transfusion). Sternal marrow was replaced by fibrous tissue.

During the first three weeks in the hospital, 1,300 r units of Roentgen radiation were given to the area of the pelvis following which the uterine bleeding stopped. She also received 8 blood transfusions which elevated her count to Hgb, 67 per cent (10.4 Gm), RBC, 4.62, WBC, 3,050. For the next several months her condition was fairly good except for an occasional transfusion reaction. In five months she had received 44 transfusions, in spite of which her count had been gradually dropping, being Hgb 20 per cent, RBC 0.93, WBC 900 at this time. From this point her condition slowly deteriorated. Transfusions were

tions became quite frequent, even with washed red cells, epistaxes became troublesome and required packing, petechiae and ecchymoses became more numerous

Eight and a half months after admission, following her sixty-fifth transfusion, she developed a thrombophlebitis of the left arm. In spite of the usual methods of therapy, the process continued to spread and the patient expired eight days later. Permission to perform an autopsy was refused. Post mortem liver biopsy revealed a hemosiderosis associated with increased fibrosis of the periportal tissues (very early cirrhosis).

Comment This 37 year old woman had an aplastic anemia of unknown etiology. She had taken "Anacin" and "Midol" intermittently for years but none of the usually incriminated drugs or agents had played an etiologic role. We speculated on the possibility that this case might have represented one of those rare instances, if indeed such conditions occur at all, in which true marrow 'exhaustion' occurs from too protracted and severe a drain. Her menorrhagia dated back to the menarche 23 years previously. This is, of course, purely speculative, since we know nothing about the nature of the pelvic tumor or the blood findings at any time during the previous twenty-three years. Unfortunately, no postmortem examination was performed, but the liver biopsy showed unmistakable signs of early cirrhosis about nine months after the first transfusion. Actually, it cannot be assumed that this patient started depositing iron in the beginning since she was still bleeding and her transfusions served as replacement therapy. Thus, her early cirrhosis occurred in a period of less than eight months.

Case 5 Victoria G

The patient, a Negro female, was 43 years old when she first entered the hospital because of weakness, dyspnea, orthopnea and bronchitis of one year's duration. For six weeks before admission she had noted vague chest pains, moderate epistaxes, blood streaked sputum, and paresthesias of the hands and feet. She had had typhoid-malaria during childhood, and anti-luetic therapy with arsenic and bismuth some years previously. She was well developed and well nourished, quite pale, moderately dyspneic, and coughed frequently. The heart was enlarged both to the right and left, loud systolic and presystolic murmurs were heard at the apex and the systolic murmur at the base was heard transmitted to the vessels of the neck. There was dullness at both bases, breath sounds were distant and rales were noted in the right base. The liver was felt 4 cm. below the costal margin and had a sharp tender border. The spleen was not palpable. External hemorrhoids were present. Moderate nonpitting edema of both ankles was noted. Fundoscopic examination revealed nothing remarkable.

Examination of urines, stools and serologic blood tests were noncontributory. The gastric contents contained 40° free and 60° total acid. NPN, 26 mg. per 100 cc., creatinine, 1.5 mg. per 100 cc., icterus index 7 units. Hgb., 12 per cent (1.8 Gm.), RBC, 0.70, WBC, 9,300, polys, 71 (bands 15), eosinophils, 6, basophils, 2, lymphocytes, 21, hyperchromia 2 plus, anisocytosis, 3 plus. Tests for sickling were negative. The marrow was hypercellular, megakaryocytes were normal, primitive red cells dominated erythropoiesis, but there were no megaloblasts, granulopoiesis showed a slight left shift with numerous giant band forms and megalometamyelocytes, eosinophils were extremely numerous. X-rays of the chest confirmed the cardiac enlargement, while those of the gastrointestinal tract were negative. The patient was given digitalis, diuretin, ammonium chloride, parenteral liver extract and 3 transfusions of 500 cc. of blood. She felt better and left the hospital in three weeks. No diagnosis was established.

During the next four and one quarter years she was treated at three different hospitals, receiving a total of 50 blood transfusions and a course of bismuth and arsenic. At the end of this time she was readmitted to the Cook County Hospital with symptoms essentially similar to the original ones. She appeared older than her chronologic age of 47 and was quite pale and dyspneic. The liver now was 10 cm. below the costal margin, and was firm and tender. The spleen was palpable on deep inspiration. Mild pitting edema of the ankles was present. At this time she had Hgb., 15 per cent (2.3 Gm.), RBC, 0.69,

WBC 11,450, polys 68, bands 12, countophils 1, lymphocytes 2, monocytes 4. Urinalysis was negative. Icteric index 14 units. Serum proteins 6.5 Gm, albumin 3.2 Gm, globulin 3.3 Gm, blood

FIG. 8. Great increase in iron deposition both in pancreatic acini and islets of Langerhans (Iron Stain) Case 5. 320 X.

FIG. 9. GREAT INCREASE IN HEMOSIDERIN IN LIVER (IRON STAIN) CASE 5. 160 X.

cultures and blood and spinal fluid serology negative. In spite of 9 blood transfusions during an eighteen day period, supplemented by oral iron and parenteral liver therapy, her blood count remained at Hgb,

19 per cent, RBC, 0.93, WBC, 14,500, polys, 64 (bands 29), eosinophils, 13, lymphocytes, 21, monocytes, 1, metamyelocytes, 1. Marrow findings were unchanged.

At this time a splenic inhibition was considered as responsible for preventing the maturation of the erythrocytes and it was decided to perform a splenectomy. This was performed after a preliminary series of transfusions, elevating the blood count to Hgb, 58 per cent, RBC 3.68, WBC 6,300. In spite of the preparation and the administration of 1,000 cc. of blood during operation, the patient went into shock immediately after the removal of the spleen. She responded to antishock management and for the first few days postoperatively seemed to be in fair condition. However, she developed bronchopneumonia and died seven days after the operation. During this period, 3 more transfusions had been given. Her last blood count showed Hgb, 60 per cent, RBC, 3.76, WBC, 25,600, polys, 83 (bands 30), basophils, 1, lymphocytes, 15, monocytes, 1.

Pertinent postmortem findings were Hemosiderosis and cirrhosis of the liver (3,160 Gm), hemosiderosis of the pancreas and abdominal lymph nodes, hyperplasia of the marrow, multiple accessory spleens, terminal bronchopneumonia, fatty degeneration of the myocardium, and acute edema of the lungs. The extirpated spleen weighed 780 Gm and showed a marked diffuse fibrosis. About thirty accessory spleens, measuring from 2 mm to 4 cm, and weighing a total of about 80 Gm, were also removed at operation.

Comment. This 43 year old Negress had a profound anemia whose etiology, as that of case 3 which it most closely resembled, was never satisfactorily established.⁴² The anemia was characterized by a hypercellular erythroblastic marrow which showed evidences of a maturation arrest at a primitive stage and did not respond to any of the known anti-anemia preparations. Life was maintained by substitution therapy consisting of 75 blood transfusions during four and one-half years. This patient did not develop diabetes. Whether skin changes occurred is not known. The remarkable enlargement of the liver was on the basis of the marked hemosiderosis and fibrosis. Undoubtedly these changes made her a worse surgical risk and contributed to the fatal outcome of the splenectomy.

SUMMARY

1. Five patients who died as a result of a variety of diseases, all characterized by severe anemia for which numerous transfusions had been given, and all of whom developed features of hemochromatosis are presented.
2. Eight similar cases found in the literature are summarized.
3. It is postulated that the hemochromatosis developing in these patients is the end result of the deposition and subsequently irritating action of the excess amounts of iron in the parenchymatous tissues.
4. The underlying anemia and the not infrequent transfusion reactions are thought to act as predisposing factors for the development of exogenous hemochromatosis.
5. The name *Exogenous Hemochromatosis* is proposed for this syndrome.
6. The clinical similarities and dissimilarities and the differences in pathogenesis between exogenous and endogenous hemochromatosis are discussed.

HISTOCHEMICAL METHODS APPLIED TO HEMATOLOGY*

By JACK J. RHEINGOLD, M.D., AND GEORGE B. WISLOCKI, M.D.

CHEMICAL cytology deals with the chemical characterization of substances in their natural locations within cells. Its principal aim is to provide a morphologic basis for the understanding of the chemical and functional activities of cells. It attempts to develop histologic staining methods which will have chemical significance and which will characterize and differentiate various kinds of cellular lipids, carbohydrates, proteins, enzymes and inorganic substances. In addition to the use of staining methods, the chemical and physical milieu of cells can be explored by other procedures and techniques, for example, by means of polarized light, ultraviolet light, x-ray diffraction spectra and the electron microscope, to name a few. The present investigation involves the application of a number of methods of chemical cytology to the cells of blood and bone marrow. The results illustrate, we hope, how, by contributing to an understanding of the chemical composition and activity of blood cells, chemical histology can advance the subject of hematology.

The chemical cytology of normal blood and bone marrow has been under investigation for some time in this laboratory. Previous papers have concerned the use of various histochemical procedures for the demonstration of lipids, nucleoproteins, glycogen, acid and alkaline phosphatases, and the phenomenon of metachromasia (Wislocki and Dempsey¹, Wislocki, Bunting and Dempsey²). The present study is a continuation of these lines of investigation. Additional data are presented, including information obtained from a more extensive examination of human blood cells.

The previous observations were carried out mainly on deparaffinized sections of bone marrow. We have now adapted some of the histochemical procedures for use on imprint preparations of bone marrow and on smears of peripheral blood. As a result of these modifications and also from a growing familiarity with the various techniques, our previous observations have been considerably extended. The results of the present study will be presented under the headings of lipids, nucleoproteins, metachromasia, phosphatases and glycogen. In addition to the two papers referred to above, the few other existing investigations in this field will be briefly cited or reviewed.

MATERIAL AND METHODS

The material for the present study was obtained from 2 young rhesus monkeys and a number of human subjects †. Blocks of marrow from the femurs of the 2

From the Department of Anatomy, Harvard Medical School, Boston, Mass.

* This work was done in part under a grant from the American Cancer Society on the recommendation of the Committee on Growth of the National Research Council to Dr. George Wislocki, Department of Anatomy, Harvard Medical School, and in part under a grant from the U. S. Public Health Service to Dr. William Dameshek, Department of Medicine, Tufts College Medical School, for the study of Mediterranean anemia.

† The human material was obtained from the Hematological Laboratory of The Pratt Diagnostic Hospital, Boston, Massachusetts, through the interest and courtesy of Dr. William Dameshek.

monkeys were immersed in various fixatives, and from others touch or imprint preparations made on glass slides were placed in identical fixatives *

Human material consisted of smears of bone marrow and peripheral blood from normal subjects as well as from patients suffering from pernicious anemia, multiple myeloma, Gaucher's disease, lymphocytic, myelocytic and monocytic leukemia, and other pathologic conditions. Peripheral blood was obtained by finger puncture, and marrow by aspiration, usually from the sternum.

For the staining of lipids with sudan black B, blocks of marrow and imprints were fixed in 10 per cent neutral formalin. Subsequently, frozen sections and imprints were immersed briefly in 70 per cent alcohol and stained in a saturated solution of sudan black B for one and seven minutes. Smears of peripheral blood and bone marrow were also fixed by immersion in 70 per cent alcohol for a few seconds, or by placing them for five seconds in a mixture of 10 per cent formalin—1 part, and 95 per cent ethyl alcohol—9 parts (Bailiff and Kimbrough³). These preparations were then stained in sudan black B for periods ranging from ten minutes to one hour. They were dipped briefly in 70 per cent alcohol and dried. They could then be counterstained, if desired, with Wright or Wright-Giemsa stain.

Nuclear basophilia was studied by means of the Feulgen reaction following fixation of pieces of bone marrow in Zenker's fluid. For smears of marrow and blood, fixation in 95 per cent alcohol for thirty seconds was utilized and found to be very satisfactory. Light green was used as a counterstain.

For the study of cytoplasmic basophilia, imprints, smears, and blocks of tissue were fixed in Zenker's fluid and stained with eosin and methylene blue. To determine whether cytoplasmic basophilia present in some cells might be due to the presence of ribonucleoprotein, control sections were treated with ribonuclease[†] before staining them. For this purpose, the sections were digested at a temperature of 60 C for three hours in a 0.1 per cent crystalline ribonuclease solution buffered with sodium barbital to a pH of 6.75.

Another means for the characterization of cellular basophilia consists of measuring the dye-binding capacity of tissue elements photometrically for methylene blue over a range of pH. For this purpose, the tissues were fixed in Zenker's fluid, imbedded in paraffin, sectioned at 5 micra and mounted on glass slides. After deparaffinization, the sections were stained in methylene blue according to the method described by Dempsey and Singer⁴ and Dempsey, Wislocki and Singer⁵. The intensity of staining of various substances was determined by measurements made with a photometer (see fig. 1, Dempsey, Bunting, Singer and Wislocki⁶). The figures obtained for light absorption were plotted against pH to form a graph relating dye-binding to the acidity of the staining solution.

Staining of metachromatic substances was carried out on smears, imprints and

* We are indebted to Mrs. Edith Herman for her assistance in the preparation of the material by the various techniques employed.

† Crystalline ribonuclease was kindly provided by Dr. M. Kunitz of the Rockefeller Institute for Medical Research, Princeton, N. J.

paraffin sections of tissues fixed in 4 per cent basic lead acetate,^{*} according to the method of Holmgren.⁷ Sections cut at 4 micra were stained in a 0.5 aqueous solution of toluidin blue, resulting in a lavender or purple coloration of the metachromatic components of the tissue. Metachromasia observed following this procedure may be due to the presence of mucopolysaccharides, ribonucleoproteins or substances of unknown composition.⁸ That attributable to ribonucleoprotein can be identified by exposing control sections to ribonuclease (see above).

For demonstrating the presence of glycogen, smears, imprints and blocks of tissue were fixed in a solution of absolute alcohol, formalin and picric acid (Rossman's fluid). Sections and imprints were then stained by the Bauer-Feulgen method. Since glycogen is dissolved by saliva, control sections so exposed were prepared.

Alkaline phosphatase was demonstrated by the Gomori method,⁹ as modified by Dempsey and Deane.¹⁰ Blocks of tissue, smears and imprints were fixed in chilled 80 per cent alcohol. The sections and imprints were then incubated for three and six hours in a solution of sodium glycerophosphate at pH 9.4.

LIPIDS

Foreword. Increasing attention is being accorded sudan black B as a histologic stain for lipids. With this dye, Sheehan¹²⁻¹⁹ observed briefly that the leucocytes of human blood became variously tinged. The neutrophilic leucocytes were filled with small, deeply stained granules, whereas the larger granules of the eosinophilic leucocytes appeared to possess merely a surface layer of lipid. The monocytes usually contained lipid granules, while the small and large lymphocytes were always quite free. Myelocytes possessed many sudanophilic granules, and myeloblasts usually had a small number, while lymphoblasts showed no sudanophilia at all. McManus,¹³ studying films of human blood and marrow stained with sudan black B, reported briefly that the cytoplasm of the neutrophilic leucocytes was packed with fine sudanophilic granules, whereas the lymphocytes and monocytes were unstained. Furthermore, granules stained by sudan black B were reported as being present in the cells of the late myeloblast series.¹⁴ Ralph¹⁴ presented an extremely brief report on human blood, examined with sudan black B, to the effect that the granules of neutrophils, eosinophiles and monocytes contained phospholipids as well as lipids extractable with acetone. Lymphocytes and thromboplastids, on the contrary, were said to contain no phospholipids.

Wislocki and Dempsey¹ studied bone marrow and peripheral blood of several young rhesus monkeys in formalin-fixed frozen sections stained with sudan black B. They verified the fact that both neutrophilic and eosinophilic leucocytes of the circulating blood show intense black staining of their granules as do also the corresponding myelocytes of the bone marrow. Lymphocytes of the blood and tissues did not contain lipid particles, but cells which were diagnosed as being

* Merck's reagent lead subacetate ($\text{Pb}(\text{CH}_2\text{CO}_2)_2 \cdot \text{Pb}(\text{OH})_2$ mol. wt. 566.52) has been used. The stock must be protected from exposure to air since combination with carbon dioxide results in an insoluble compound. The 4 per cent solution should be made up freshly before using.

monocytes appeared to have a few black particles in their cytoplasm. In megakaryocytes, minute sudanophilic particles were observed, and in blood platelets similar lipoidal dots were encountered. In a subsequent study,² evidence was offered suggesting that the sudanophilic material in the cytoplasm of the megakaryocytes might represent mitochondria.

Bailiff and Kimbrough³ examined normal and abnormal peripheral human blood stained with sudan black B, followed by May-Grunwald Giemsa stain to aid in the differentiation of cell types. They noted that the granules of the eosinophiles were sudanophilic and possessed unstained, clear centers. Basophilic leucocytes, lymphocytes and monocytes were unstained.

From the previous account it will be noted that there is general agreement regarding the behavior of the granular leucocytes, myelocytes and lymphocytes. Of the monocytes, McManus,¹³ as well as Bailiff and Kimbrough,³ claim that they do not stain, whereas Sheehan,¹² Ralph,¹⁴ and Wislocki and Dempsey¹ describe them as being variously tinged.

Excepting Bailiff and Kimbrough, none of the investigators specifically mentions the reaction of the basophilic leucocytes. Because these elements are relatively scarce and with the technic employed difficult to identify, Wislocki and Dempsey¹ and Wislocki, Bunting and Dempsey² turned their attention to tissue mast cells. In formalin-fixed frozen sections of several human organs, including uterine cervix and mammary gland, they observed mast cells in which a portion of the normal complement of granules was stained by sudan black. In contrast to the partial or incomplete staining of the granules of mast cells, the granules of tissue eosinophiles were completely and readily stained in similarly prepared formalin-fixed, frozen sections.² Meanwhile, Montagna and Noback¹⁵ have reported that sudan black B reveals stained granules in the mast cells of the rat, when applied to frozen sections of tissues fixed in formal calcium-cadmium.

Observations. The present observations on sudanophilia have been made upon human blood cells from both blood stream and bone marrow. Sudanophilic granules are present in the neutrophilic leucocyte-precursors from the time when specific granules first make their appearance. The sudanophilic granules, staining a grayish brown to black color, are in evidence throughout the series and from their number and size appear to be identical with the specific neutrophilic granulations (fig. 2c). In the myelocyte stage they can be seen overlying the nucleus.

The granules of the eosinophilic leucocytes and of the corresponding myelocytes are sudanophilic. As noted by several investigators, the granules are characterized by a darker, sudanophilic periphery and a clearer, possibly totally unstained, interior (fig. 2a). This peculiarity differentiates their granules from those of the neutrophilic leucocytes.

The basophilic leucocytes in the peripheral blood of several patients with chronic myelogenous leukemia have been examined. Their granules prove to be sudanophilic (fig. 2d), varying in size and ranging in intensity of staining in individual cells from pale gray to deep black. Many of the smaller granules stain solidly black, whereas the larger granules are as a rule

cosinophiles exhibit marked uniformity in regard to depth of staining and size

In the blood of 2 patients in which the monocytes were increased and hence readily identifiable, a variable scattering of sudanophilic cytoplasmic particles was observed (fig 2f). These varied in size and number from a few faint dots up to a dusting of the cytoplasm with quite evident black particles. Since a counterstain tends to obscure these faint particles, monocytes are best studied without its use.

FIG. 1. Curves illustrating and comparing the dye-binding capacity of the cytoplasm of megakaryocytes, mast cell granules, Nissl substance and the hyaline matrix of cartilage. The several tissues were fixed in Zenker's fluid, sectioned, stained with methylene blue, and their dye-binding capacity determined according to a method presented in detail elsewhere (Dempsey et al.⁶). The cytoplasm of megakaryocytes fails to stain below pH 4.0, in this respect being identical with characteristic nucleoproteins such as Nissl substance or cell nuclei. The granules of mast cells and the matrix of hyaline cartilage, on the contrary, exhibit very much stronger acid dissociation, so that staining is not abolished even at pH 1.6 (cf. Wislocki and Dempsey¹ and Dempsey et al.⁶). Their signatures are characteristic of sulfate-containing acid mucopolysaccharides.

In human material, sudanophilia was not observed in either megakaryocytes or platelets. In the megakaryocytes and platelets of the monkey, on the contrary, minute sudanophilic dots have been described,¹ and from their shape, size and number these appear to be mitochondria.² In the smears of human material prepared in the manner described, conditions are possibly not so favorable for the staining of these small particles.

We have not encountered lipids in lymphocytes in any of our preparations.

Gaucher cells have not been described as being sudanophilic, but they are rich in cerebrosides (Thannhauser³⁸). Because sudan black B appears to have an affinity for a greater variety of lipids than the other sudan dyes currently used in histology, we exposed smears known to contain Gaucher cells to this dye. No sudanophilic

FIG 2 Individual cells from smears of human bone marrow, fixed in 70 per cent alcohol for a few seconds, stained with sudan black B for 10 minutes, and with the exception of d, counterstained with Wright-Giemsa stain. All cells in figures 2 and 3 were drawn with a $\times 10$ ocular and $\times 90$ objective.

a An eosinophilic myelocyte containing granules of uniform size, each composed of a sudanophilic shell surrounding an unstained core.

b Two adult erythrocytes showing a dark tinge, superimposed on their normal color, following exposure to sudan black.

c Orthochromatic nucleated red blood cell, whose cytoplasm is tinged by sudan black, but not so deeply as adult erythrocytes.

d Basophilic leucocyte, stained only with sudan black, exemplifying the variation in size of the granules, and their lesser number as compared with eosinophilic granules. Each granule exhibits a dark periphery and light center. The granules in occasional basophilic leucocytes are completely blackened, more especially those of smallest size.

e Polymorphonuclear neutrophilic leucocyte, revealing sudanophilia of its specific granules.

f Monocyte illustrating the presence of various sized sudanophilic particles within its cytoplasm.

FIG 3 (a, b and c) Individual cells from smears of peripheral human blood and bone marrow fixed for 30 seconds in 95 per cent alcohol, then stained by the Feulgen method which is specific for desoxyribonucleoprotein. Counterstained with light green. (d) A megakaryocyte from human bone marrow, stained by the Bauer-Feulgen technique.

a Two adult red blood cells, one containing a Howell-Jolly body which is stained red and is Feulgen positive, and three blood platelets which are negative.

b A polymorphonuclear leucocyte, the nucleus of which is Feulgen positive.

c A megakaryocyte whose nucleus also is Feulgen positive. It was observed above that blood platelets are Feulgen negative, and it is noteworthy that the cytoplasm of megakaryocytes is also negative.

d A megakaryocyte from a section of human bone marrow which was fixed in a solution of absolute alcohol, formalin and picric acid, then stained by the Bauer-Feulgen technique and counterstained with light green. Note pinkish-lavender color of cytoplasm and the scattered deeper staining granules in the neighborhood of the nucleus. Unlike the Bauer-Feulgen reaction of true glycogen encountered in neutrophilic leucocytes, this reaction in the cytoplasm of human megakaryocytes is not prevented by

material could be demonstrated, and it must be concluded that, unlike some other phospholipids, cerebroside has no affinity for sudan black.

We have observed a faint staining of the red blood cells by sudan black. Adult erythrocytes and the antecedent orthochromatic and polychromatic nucleated red blood cells are diffusely and faintly tinged (fig. 2b, c). The more mature the cell stage, and the longer the preparations are exposed to the dye, the darker the cells become. According to Parpart and Dziemian,¹⁶ the structural meshwork (stromata) of the red blood cells is composed chiefly of lipids and proteins. Among the lipids, phospholipids predominate, while cholesterol makes up the remainder (cf. Hober¹⁷). Nevertheless, Baker¹⁸ found tests for phospholipids inconclusive in the erythrocytes of the frog and mouse. In view of these considerations, we are not prepared to interpret the observed staining of the erythrocytes by sudan black B.

NUCLEOPROTEINS

Foreword. Two kinds of nucleic acids exist in cells, depending upon the nature of the sugar incorporated into their structure. One, containing a desoxyribose sugar, is called desoxyribonucleic acid, whereas the second contains a ribose sugar and is designated as ribonucleic acid. Nucleic acids are strongly charged compounds and have a strong affinity for basic dyes. Moreover, their basophilia is not destroyed by conjugation with proteins so that the nucleoproteins are also strongly basophilic.

Although nucleoproteins have long been known to display pronounced basophilia and therefore to be among the substances in tissues which react with basic dyes, the positive identification of them and their accurate localization in cells have only recently been accomplished. Three methods have been developed which are of importance in this regard. These are the staining method of Feulgen and Rossenbeck¹⁸ for desoxyribonucleoprotein, the use of ribonuclease developed by Dubos,¹⁹ Brachet²⁰ and Kunitz,²¹ and the utilization by Caspersson²² of the specific ultraviolet absorption of nucleoproteins. To these should be added a recent method for measuring by photometric means the dye-binding capacity of tissue elements over a range of pH (Dempsey and Singer⁴, Dempsey, Wislocki and Singer⁵).

The Feulgen method consists in the freeing of the aldehyde groups of the desoxyribose sugar by acid hydrolysis followed by the Schiff test for aldehydes. The procedure is apparently specific for desoxyribonucleoprotein (cf. Stowell²³) and is confined entirely to the nuclei of mammalian cells or to the immediate products of their disintegration or dissolution, as will be shown below. The nucleolus is Feulgen-negative because it is composed of ribonucleoprotein.

The discovery and preparation of an enzyme capable of depolymerizing ribonucleic acid paved the way for the cytologic localization of ribonucleoproteins. Brachet²⁰ described the ability of ribonuclease to abolish cytoplasmic basophilia in a variety of animal cells, including pancreatic, hepatic and intestinal epithelium, nerve cells and lymphocytes. Wislocki and Dempsey¹ observed the disappearance of cytoplasmic basophilia from erythroblasts, myelocytes, lymphocytes and some other basophilic cells of the marrow following this procedure. More recently, Wislocki, Bunting and Dempsey² have noticed a moderate basophilia of

the cytoplasm of megakaryocytes. This basophilia is abolished by treatment with ribonuclease, indicating the presence of ribonucleoprotein in these cells. In addition to various cytoplasmic structures, a number of investigators have noted the disappearance of basophilic staining in the nucleolus after treatment with ribonuclease.

Other basophilic substances, occurring variously in the cytoplasm and in ground substances, may be composed of mucopolysaccharides or of substances of unknown composition. With the photometric method referred to above, which registers the intensity of staining of selected cell constituents over a range of pH, characteristic and specific curves or "signatures" may be obtained for a variety of basophilic substances, including nucleoproteins and mucopolysaccharides.

Observations. In the present study we have continued the use of these methods in the study of blood. By the Feulgen method the cell nuclei of human marrow stand out distinctly as reddish purple objects, indicating the presence of desoxyribonucleoproteins (fig. 3). The dense chromatin of the polychromatic normoblasts stains more intensely than the finer chromatin of the younger stages of the red blood cells. The nucleoli are unstained. Imprints of bone marrow stained less well than histologic sections.

Howell-Jolly bodies and blood platelets were noteworthy. The Howell-Jolly bodies were stained by the Feulgen technic, indicating that they are nuclear material consisting of desoxyribonucleoprotein (fig. 3a). Blood platelets, on the contrary, were negative, indicating that they contain no nuclear material (fig. 3a). Voit and Kempa²⁴ have described a positive reaction for platelets, when stained in thick films, but our observations do not bear out their contention. The delicacy of the reaction in the Howell-Jolly bodies suggests that the reaction would occur similarly in platelets provided that they contained nuclear material. In accord with the negative findings in platelets, it is noteworthy that no Feulgen positive material is encountered in the cytoplasm of megakaryocytes (fig. 3c).

It should be recorded also that neither the basophilic material in the cytoplasm of reticulocytes nor the cytoplasmic stippling of erythrocytes reacts at all, indicating that neither of these structures contains desoxyribonucleoprotein.

The use of ribonuclease on human marrow cells confirms the previous observations of Wislocki and Dempsey¹ on monkey marrow. The cytoplasmic basophilia of the red blood cells precursors, as well as of the basophilic stem cells of the leucocytes, is abolished by the use of this enzyme. This holds true of myeloblasts and promyelocytes, as well as megakaryocytes. The cytoplasmic basophilia of lymphocytes and plasma cells is likewise abolished.

These findings are of interest in view of the recent important discovery that a major function of lymphocytes is to produce globulins which participate in immune reactions (Dougherty and White²⁵, Ehrlich and Harris²⁶). Consequently the globulin synthesis of the lymphocytes can now be related to the cytoplasmic nucleoproteins which are responsible for the basophilic properties of the cells (Dempsey and Wislocki³²).

By means of the photometric method, described above, for the characterization of basophilic staining, we have concerned ourselves with the cytoplasmic baso-

philia of megakaryocytes. The cytoplasm of this cell interested us particularly because Wislocki, Bunting and Dempsey² had arrived at the conclusion, after some previous uncertainty, that it exhibits a moderate amount of basophilia attributable to ribonucleoprotein. The "signature" obtained by the photometric method confirms this conclusion (fig. 1). The curve for the cytoplasm coincides, in regard to degree of acid dissociation and extinction around pH 4.0, with Nissl substance, a nucleoprotein which fails characteristically to stain below pH 4. For comparison, the graph contains curves for the hyaline matrix of cartilage and the granules of mast cells, both of which consist of strongly acid mucopolysaccharides, the staining of which is not abolished even at pH 1½. Thus we have proof from the use of ribonuclease, as well as from the photometric signature, that the cytoplasm of megakaryocytes contains ribonucleoprotein. We have not succeeded as yet in testing blood platelets with either ribonuclease or by the photometric method.

METACHROMASIA

Metachromasia is a property, which some basophilic substances possess, of changing the color of certain dyes such as toluidin blue or thionin from blue to red. The principal group of substances exhibiting metachromasia is the acid mucopolysaccharides, but nucleoproteins, after certain methods of fixation, also stain metachromatically. Many of the cells of bone marrow exhibit variably faint metachromatic reactions which are prevented by the use of ribonuclease, a result indicating that the reactions are due to ribonucleoproteins. For example, the cytoplasm of megakaryocytes, following fixation in 4 per cent basic lead acetate, especially in the bone marrow of guinea pigs, is noticeably metachromatic when stained with a 0.5 per cent aqueous solution of toluidin blue, but this staining is prevented by the use of ribonuclease (Wislocki, Bunting and Dempsey²⁷).

The granules of the mast cells of the connective tissues are intensely metachromatic due to the presence of an acid mucopolysaccharide, possibly heparin as claimed by Holmgren and Wilander.³³ This reaction is not prevented by ribonuclease (Wislocki, Bunting, and Dempsey²) and the granules yield a photometric signature characteristic of acid mucopolysaccharides (fig. 1). The granules of basophilic leucocytes are known to exhibit metachromasia, but we have not tested them photometrically.

PHOSPHATASE

Foreword. The amount and distribution of alkaline phosphatase in various blood cells have been investigated to some degree in a variety of animals. Wachstein²⁸ has described this enzyme in normal and abnormal cells of human blood and bone marrow, according to him, it is not present in red blood cells, lymphocytes, monocytes or eosinophilic leucocytes of circulating blood, but is present in a variable number of neutrophilic leucocytes. In marrow, staining was uneven and involved neutrophilic leucocytes and occasional nucleated red cells. Megakaryocytes were as a rule negative. Wislocki and Dempsey¹ have described various features of the distribution of alkaline phosphatase in the hemopoietic tissue and blood of

rhesus monkeys, while Deane²⁹ has reported on its presence in the leucocytes of rats. The last-mentioned investigator used nucleic acid, fructose diphosphate, glucose-6-phosphate and adenylic acid as substrates in addition to glycerophosphate. Recognizable differences in blood cells, following the use of these several substrates, have not been very great.

Wislocki and Dempsey¹ report upon the presence of alkaline phosphatase in variable quantities in the cytoplasm of polymorphonuclear neutrophilic leucocytes, metamyelocytes, myelocytes and lymphocytes. As a rule, the enzyme occurs in both cytoplasm and nucleus. No information appears to exist on the occurrence of phosphatase in basophilic leucocytes of either blood or marrow. However, the granules of tissue mast cells of the rat have been shown to contain alkaline phosphatase by Noback and Montagna³⁴ and Wislocki and Dempsey.¹ Contrariwise, in human tissue eosinophiles, Wislocki, Bunting and Dempsey² encountered none of the enzyme. In keeping with an observation on human marrow (Wachstein³⁸), little or no phosphatase was observed in the cytoplasm of megakaryocytes in the bone marrow of the monkey, and insofar as platelets could be evaluated, none was demonstrable.

Only brief references exist to the occurrence of acid phosphatase in the cells of the hemopoietic tissue. Gomori¹⁰ reported the blood cells of all species studied as being negative. Deane²⁹ refers briefly once to its occurrence in occasional polymorphonuclear leucocytes in the rat. In the granules of the mast cells of rats, both Montagna and Noback¹⁵ and Wislocki, Bunting and Dempsey² have described acid phosphatase. In the granules of human tissue eosinophiles the latter investigators have not encountered any.

Observations. The present observations concern the demonstration of acid and alkaline phosphatases in both tissue sections and imprints of rhesus monkey's bone marrow with glycerophosphate as substrate. In the case of both enzymes there is far more phosphatase visible in the imprint preparations than in the sectioned material. The procedure for both imprints and sections was identical, except that in the case of the latter, paraffin imbedding was employed. A similar experience has been reported recently by Montagna and Noback,¹⁵ who found that in mast cell granules, far less acid phosphatase was present after imbedding the tissue in paraffin than when paraffin infiltration was eliminated. These authors offer the possible suggestion that the enzyme is partially denatured during infiltration in paraffin at high temperatures.

In the present material, alkaline phosphatase is readily identified in neutrophilic leucocytes, metamyelocytes and myelocytes, being most abundant in the latter. It is diffusely and variably present in both cytoplasm and nuclei. The cytoplasm of the megakaryocytes shows a diffuse faint staining. The nucleated red cells are uniformly negative in both cytoplasm and nuclei.

Imprints of monkey marrow prepared for acid phosphatase reveal an abundance of this enzyme in contrast to its almost complete absence in sectioned material. It is predominantly nuclear in location, staining the nuclei of nearly all of the cells present in the marrow. A few of the cell types can be definitely identified. Myelo-

cytes, in addition to diffuse nuclear and cytoplasmic staining, often exhibit a brownish granulation of their cytoplasm. Metamyelocytes and polymorphonuclear leucocytes are readily identified by brown staining of their nuclei. Nucleated red cells and megakaryocytes are also recognizable by differentiation of their nuclei.

GLYCOGEN

Foreword. Neukirch,³¹ in 1910, observed material stained by iodine or Best's carmine method for glycogen in human neutrophilic leucocytes of inflammatory exudates. The material was soluble in saliva and consequently he decided that it must be glycogen or some closely related carbohydrate. Similarly, Stahl, Horstmann and Hilsnitz,³⁶ utilizing iodine vapor, observed staining of the granules of the neutrophilic metamyelocytes and leucocytes, this they attributed to the presence of glycogen without, however, testing it with saliva.

In human blood platelets Neukirch³¹ found central bodies tinged by iodine and stainable with Best's carmine, but these were insoluble in saliva. Stahl, Horstmann and Hilsnitz³⁶ also encountered iodophilic granules in human platelets as well as a very few, seemingly identical cytoplasmic particles in megakaryocytes. However, they did not test any of these granules for their solubility in saliva.

Wislocki and Dempsey¹ investigated the presence of glycogen in the blood cells of rhesus monkeys by means of the Bauer-Feulgen technic and by an ammoniacal silver nitrate method devised by Mitchell and Wislocki.³⁰ The diagnosis of glycogen was checked by routine saliva-treated controls. Both methods were successful and positive when applied to appropriately fixed material. Glycogen was identified with regularity in bone marrow in the cytoplasm of neutrophilic leucocytes and metamyelocytes. None was seen in the other cell types including megakaryocytes. Glycogen was also found quite regularly in the rim of cytoplasm of the ordinary fat cells of the marrow. In peripheral blood a positive Bauer-Feulgen reaction occurred solely in the polymorphonuclear leucocytes. No glycogen was demonstrable in the blood platelets.

Observations. In the present investigation we have repeatedly observed glycogen in neutrophilic metamyelocytes and leucocytes in smears of human blood and bone marrow after staining with the Bauer-Feulgen method and using saliva controls. Glycogen is minimal in neutrophilic metamyelocytes and increases as the cells mature into leucocytes. It is not present in myeloblasts, myelocytes or the red blood cell series.

On re-examining monkey marrow, glycogen was found quite regularly in the cytoplasm of the fat cells. Moreover, in 1 young rhesus monkey, interstitial glycogen was encountered, although nothing similar was noticed in the marrows of 3 other monkeys.

In peripheral human blood, glycogen was encountered solely in the neutrophilic leucocytes. This finding agrees with those of Wagner³⁷ who has recently shown by chemical analysis that the granular leucocytes are the only carriers of glycogen in normal human blood.

As reported above, Wislocki and Dempsey found the Bauer-Feulgen and ammoni-

acal silver methods for glycogen negative in the megakaryocytes and blood platelets of rhesus monkeys. In contrast to the monkey, the megakaryocytes of human marrow are faintly Bauer-Feulgen positive, but this material is not digested by saliva (fig. 3d). Besides a faint pink color, the cytoplasm of the megakaryocyte contains a variable amount of reddish granular material. The platelets, on the contrary, like those of the monkey, are entirely negative. This finding is consistent with the results of Wagner³⁷ who identified pentose sugar in human blood platelets but found no glycogen.

Glycogen increases in amount in the neutrophilic leucocytes as they mature, and consequently it characterizes the differentiated functional state of this cell instead of its developmental stages. The glycogen does not appear to be localized or bound in the neutrophilic granules, for, as in other glycogen-bearing cells, it usually shifts by fixation to one side of the cell. Besides glycogen, the neutrophils contain alkaline phosphatase, which is extremely variable in amount and maximal in quantity in the myelocytic stages. Alkaline phosphatase is encountered in association with glycogen in various tissues of the body and its presence has been related to the synthesis of glycogen which takes place through the dephosphorylation of hexose phosphate by this enzyme (cf. Dempsey and Wislocki³²). Alkaline phosphatase within the neutrophils tends to be diffusely distributed in the cytoplasm rather than segregated in the neutrophilic granules. In mast cells, on the contrary, in which phosphatase is also abundant, the enzyme is quite definitely localized in the granules.

Confirming Wachstein,²⁸ we have observed that polymorphonuclear neutrophils which have entered the tissues in inflammatory areas contain increased amounts of alkaline phosphatase. It would be interesting to know whether simultaneously the glycogen content of the neutrophilic leucocytes is altered. Neukirch³¹ reports that the neutrophilic leucocytes in exudates contain a far greater quantity of glycogen—as revealed by iodine or Best's carmine stain—than normal leucocytes, but this observation deserves to be re-examined and checked by modern methods.

SUMMARY

In table 1 we have attempted briefly to characterize some of the principal blood cell types by means of the various histochemical methods. The data assembled in the table are derived from the present study as well as from the previous papers from this laboratory. The condensed phrases of the table should be referred back to the observations and discussions presented in the text. The spaces which are left blank do not indicate negative reactions but signify merely that critical data are still outstanding.

Besides offering new observations, the present paper summarizes some recent literature on the chemical histology of the cells of blood and bone marrow. The investigation concerns the demonstration and characterization of lipids, nucleoproteins, mucopolysaccharides, acid and alkaline phosphatases and glycogen by a variety of recently developed techniques. It serves to illustrate how histochemical procedures can be utilized to explore the chemical composition and functional activities of cells.

TABLE 1 — *Brief characterization of the principal blood cell types by histochemical reactions for lipids, nucleoproteins, phosphatases and glycogen*

Cell	Lipid (sudan black B)	Ribonucleoprot (cytoplasmic basophilia)	Acid phosphatase	Alkaline phosphatase	Glycogen (Bauer Feulgen)
Myeloblast (Sabin)	Negative	Strongly positive			Negative
Myelocyte	Granules uni- formly posi- tive	Positive	Nucleus posi- tive	Positive in cy- toplasm and nucleus	Negative
Metamyelocyte	Granules uni- formly posi- tive	Negative	Nucleus positive	Positive in cy- toplasm and nucleus	Faintly posi- tive
Polyneut	Granules uni- formly posi- tive	Negative	Nucleus posi- tive	Variably pos in cytoplasm and nucleus	Positive
Eosin Myelo- cytes and Leuco	Granules uni- formly posi- tive				
Tissue Eosin	Granules uni- formly posi- tive	Negative	Negative	Negative	Negative
Baso Leuco	Granules vari- ably positive				
Mast Cells	Granules vari- ably positive	Granules negative	Nucleus neg Granules pos	Nucleus neg Granules pos	Negative
Early Ery thro- blast	Negative	Strongly positive			Negative
Late Erythro- blast	Cytoplasm very faintly tinged	Positive	Nucleus posi- tive		Negative
Normoblast	Cytoplasm faintly tinged		Nucleus posi- tive		Negative
Erythrocyte	Faintly tinged	Negative		Negative	
Megakaryocyte	Minute dots (monkey) None (man)	Moderately positive	Nucleus posi- tive	Cytoplasm faintly pos	Negative (mon- key), Positive (man), Saliva- insoluble
Blood platelets	Minute dots (monkey) None (man)				Negative
Lymphocytes	Negative	Strongly positive		Cytoplasm and nucleus variably pos	Negative
Monocyte	Minute gran- ules			Negative (cit Wachstein)	Negative

CLOTTING OF PLASMA AND SILICONE SURFACES

By THOMAS B PATTON, M D , ARNOLD G WARE, PH D , AND WALTER H SEEGBERS, PH D

THE USE of silicone surfaces for blood clotting studies offers new technical approaches to the problems concerned. In their pioneer work, Jaques, Fiddell, Feldsted and Macdonald¹ indicated the possibility that plasma may clot independently of platelet action. They suggest, as others have, that plasma may contain a soluble factor which will initiate clotting. In their studies, the platelet concentrations were lowered by centrifugation at low speeds only to about 3,000 per mm³.

We believed that with the use of high speed centrifugation and silicone surfaces blood plasma would remain fluid indefinitely. All the platelets would be removed and even if some should rupture, the thromboplastin released might be expected to be removed by sedimentation in accordance with the work described by Chargin^{2, 3}.

We followed the venipuncture technic described¹ and clotting was observed at unpredictable intervals. The poor results were apparently due to collapse of the vein with injury to the intima and subsequent liberation of thromboplastic substances. Slowness of withdrawal of blood also increased chances for contamination.

An improved technic was therefore devised which would eliminate tissue trauma insofar as possible. The common carotid artery of a dog was exposed, using meticulous sharp dissection. Saline was flushed over the wound and the artery, after which the wound was draped, leaving only the artery exposed. A special syringe holder (fig. 1) was designed to prevent blood from being forced into the syringe. When the puncture was made, 10 cc. of physiologic saline contained in the syringe were first injected into the artery to wash away thromboplastic substances from the needle. After thirty seconds, the blood was permitted to enter the syringe at the pressure of the blood vessel. It was not necessary to pull on the plunger. The needle and special syringe were next removed and, with the syringe in a vertical position, blood was allowed to flow against the side of the silicone centrifuge tubes. A portion was oxalated for hematocrit and control prothrombin determinations. The tubes were then placed in the rotor of a multi-speed attachment (International Equipment Co.) and spun for varying periods of time at 22-23,000 R P M. After the runs were completed, the tubes were removed and the clear plasma could be seen above the closely packed red cells which were overlaid by a whitish gray layer. To avoid contamination of the supernatant layer with the middle layer, about two thirds of the centrifuge tube was immersed in a mixture of dry ice and alcohol. The red cells, the superimposed gray layer and the lower portion of plasma were frozen solid so that the clear supernatant plasma could be decanted. Samples for prothrombin determinations were taken immediately after centrifuging and at varying periods thereafter.

Our technic eliminated many of the previously encountered erratic results, how-

This study was aided by a grant from the United States Public Health Service.

ever, it still did not enable us to obtain incoagulable plasma with any degree of certainty. We found that plasma would stay fluid for varying periods—in some runs longer than seventy-two hours at room temperatures. There would usually, however, be some fibrin formed. This occurred in silicone and in glass tubes with about equal frequency, provided centrifugation was carried out for sixty minutes or more. The rotor of the multi-speed attachment accommodates six tubes and the contents of each one would usually give somewhat different results as to time and quantity of fibrin deposited as judged by visible inspection. This fact discouraged us from making quantitative measurements of the fibrin deposits. At the end of twenty-four hours, any fibrin was removed, thrombin was added to the plasma and a clot invariably formed.

Measurements of prothrombin concentration by the two-stage method indicated

FIG. 1. Special syringe plunger holder for venipuncture. The piston is held in position by the mechanical stop and no blood can enter the syringe until the piston stop is swung to the side.

that this factor does not change appreciably in concentration if the high speed centrifugation is continued for fifteen minutes or more (table 1). Consequently, if thrombin causes the fibrin deposits mentioned above, only a small quantity is involved. It must be kept in mind that rupture of only a few platelets would liberate thromboplastin, which would perhaps not all be removed by centrifugation. Even if it were completely removed, a small amount of thrombin might first be liberated which would eventually form a fibrin deposit. If a soluble plasma factor, not concerned with platelets, initiates clotting, its action must be considered to be extremely feeble. If that view is not accepted, then it must at least be admitted that the soluble factor was sedimented in the centrifuge, or that it requires an activator removed by centrifugation.

Prothrombin analyses showed no significant change in prothrombin concentration. However, evidence for thrombin formation in the silicone plasma was obtained indirectly from Ac-globulin studies. This factor is transferred from plasma type Ac-globulin to serum type Ac-globulin through the action of thrombin.⁵ Even small amounts of thrombin will produce an effect which is easily detected. For

example, a quantity of thrombin which will not produce a clot in one hour will markedly affect plasma Ac-globulin activity. In the experiments discussed above, it was possible to detect serum type Ac-globulin when the two-stage prothrombin analyses showed no significant change. We interpret this as follows: a small amount of thrombin was formed by minute traces of thromboplastin of cellular origin. This amount of thrombin was so small that the plasma prothrombin concentration seemed not to be altered. However, this thrombin was sufficient to transform some plasma Ac-globulin to serum Ac-globulin and also sufficient to form a small fibrin deposit.

Fibrinogen was measured quantitatively in only a few experiments for reasons mentioned above. The changes in fibrinogen concentration during a typical experi-

* Minutes in centrifuge. Prothrombin determined on oxalated samples served as control, and this control was considered to have a prothrombin concentration of 100 per cent.

† F = per cent fibrinogen.

ment are recorded in table 1. Immediately after centrifugation the fibrinogen concentration, as measured by methods previously described,⁶ was lower than in the oxalate control sample. The fibrin was doubtless thrown down as soon as its aggregates formed. While the samples stood at room temperature, only small amounts of fibrin precipitated, and at twenty-two hours about 70 per cent of the original fibrinogen remained. More fibrinogen disappeared during the centrifugation period than at any other equivalent time interval. This suggests the possibility that a few platelets ruptured during the centrifugation.

SUMMARY

Blood was collected with special care and centrifuged in silicone treated glass tubes at 22–23,000 R P M. for various periods of time. Even after prolonged centrifugation, incoagulable plasma could not always be obtained. When clots formed, only a small portion of the fibrinogen was represented as fibrin. Minute amounts of thrombin cause this fibrin formation. No evidence was found to support the view that plasma may contain a soluble factor which can initiate clotting independent of platelet action.

DETERMINATION OF THE NUMBER OF ERYTHROCYTES, VOLUME OF PACKED RED CELLS, HEMOGLOBIN AND OTHER HEMATOLOGIC STANDARDS IN MEXICO CITY (ALTITUDE 7,457 FEET) STUDY MADE ON TWO HUNDRED HEALTHY PERSONS

By JAVIER ROBLES GIL, M D , AND DIEGO GONZÁLEZ TERÁN, M D

THIS work is a contribution to the knowledge of certain hematologic standards among a group of healthy residents of Mexico City. The standards studied are: volume of packed red cells, hemoglobin in grams per 100 cc of blood, red blood cell count, mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, mean corpuscular diameter, mean corpuscular thickness and sedimentation rate.

Hedin and Blix in 1890 and Daland¹ in 1891 were the first investigators to introduce the use of the hematocrit, that is, the determination by special procedures of the volume of packed red cells in a given amount of blood.

Chapin,³ Millar,⁴ Kennedy and Millikan⁵ and Ponder and Saslow⁶ believe there exists a 2 to 12 per cent factor of error in the determination of the hematocrit. They found this factor of error when measuring the cell volume by means of other procedures, such as those that include the use of dyes, proteins and tagged erythrocytes containing radioactive iron. But this factor of error, if it exists, does not invalidate the procedure for practical purposes.

The standards investigated in this work are probably of definite value in the study of the anemias. They give a clearer idea of the extent to which one of the most important functions of the blood, hematosynthesis or blood oxygenation, is modified. The red cell count alone does not give sufficient information concerning this function, since there may exist microcytosis or hypochromia or both. Furthermore, the mean corpuscular volume and the mean corpuscular hemoglobin concentration cannot be determined when only the red cell count and the hemoglobin, without the volume of packed red cells, are known.

The results obtained by different investigators are in agreement with the fact that the hematologic standards are the same for all races and economic levels.⁷⁻¹⁶ Changes due to age and sex have also been established.

Smith et al,¹⁷ Licknatzky,¹⁸ Acton and Harvey,¹⁹ Haden,²⁰ Horneffer,²¹ Barcroft et al,²² Cordero,²³ Vergara Lope,²⁴ Ocaranza,²⁵ Izquierdo²⁶ and others found an increase in the number of erythrocytes associated with an increase in the altitude. Licknatzky¹⁸ and Fitzgerald²⁷ observed an increase of hemoglobin in the same conditions. Hurtado²⁸⁻²⁹ and Andresen et al³⁰ found that the mean corpuscular volume is greater at high altitudes than at sea level. Other climatic factors have no influence, as Walters,³¹ Wintrobe³²⁻³³ and Myers and Eddy³⁴ have shown in their works.

From the Rheumatology Department of the Instituto Nacional de Cardiología and the Hematology and Microbiology Laboratories of the Hospital de Enfermedades de la Nutrición, Mexico, D F

As the result of numerous investigations, it has been stated that the normal erythrocyte count in Mexico City is in the range of 6,000,000 per cc or more. This statement does not agree with the constant results of red cell counts made in our clinic. Furthermore, the volume of packed red cells, mean corpuscular hemoglobin concentration standards of healthy persons, have never been established in Mexico City and some contradictory reports exist regarding the red cell diameter.

Considering the variation of some of the hematologic standards at different altitudes as well as the above-mentioned facts, it was deemed necessary to study them in Mexico City, because the normal standards found in other countries at sea level cannot be applied in the central plateau of Mexico, which is located at an altitude of 7,457 feet.

The establishment of hematologic standards in Mexico City is necessary not only in order to evaluate correctly the hematologic results in patients, but also to corroborate or contradict the recent discovery communicated by some investigators^{28, 29} who state that at high altitudes a well defined macrocytosis is present.

MATERIAL

One hundred normal females and 100 normal males were selected, with ages ranging from 15 to 31 years in the latter and 14 to 25 in the former. The ages of 14 and 15 were taken as the lower limits, following Osgood,¹¹ Mugrage and Andresen,³⁴ Sachs, Levine and Griffith,³⁵ Goldhamer and Fritzell,³⁶ Wintrobe,³⁷ and Williamson,³⁸ who found them to be the ages during which the stabilization of the number of red cells, hemoglobin and hematocrit begins. Williamson³⁸ obtained higher values for hemoglobin in males after the age of 20.

Our subjects were selected from different economic levels, particularly among medical and other students, draftees and nurses. All of them were in apparent good health, with well balanced diets, and most of them had lived in Mexico City since birth. A minimum of two years of residence in Mexico City was considered a necessary condition for those not born here. The average height, age and weight were 1.70 meters, 20.9 years and 59.82 kilograms in the males, and 1.58 meters, 18.04 years and 51.83 kilograms in females (table 1).

Methods and technic. All the individuals were subjected to a complete clinical examination performed by one of us (J. R. G.) and to a complete survey of their diets. Among 225 persons registered, 25 were discarded because of an existing or recent disease, deficient nutrition or a deficient constitution.

The following studies were performed on each of the selected persons: red blood cell count, volume of packed red cells, amount of hemoglobin in grams per 100 cc., mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, sedimentation rate and standard Kahn, Eagle (flocculation test) and AO₃ serologic reactions for syphilis. In addition, determinations of the mean corpuscular diameter were performed in 15 subjects. For these determinations, blood was obtained by venepuncture at the bend of the elbow after a fasting period of eight hours and according to the following technic:

1. Local cleansing with a 2 per cent iodine-alcohol solution.
2. Adjustment of tourniquet for not more than 1 minute so as to avoid alterations of blood concentration and circulation.
3. Collection of 5 cc. of blood with B-D needles number 20. The least possible traction was made in drawing the blood. The blood thus obtained was placed in flat-bottom glass tubes containing Paul-

Heller anticoagulant (0.006 Gm. of anhydrous ammonium oxalate and 0.004 Gm. of anhydrous sodium oxalate for 5 cc. of blood) and mixed thoroughly by shaking for 3 minutes

4 Collection of 4 cc. of blood for the serologic tests for syphilis

5 The tubes fitted with a rubber stopper were kept in a cool place. In every case the determinations were started within the first hour after the blood was taken

6 All the equipment used for the collection of blood and for the determination of the standards was cleansed, dried and prepared according to Wintrobe's instructions.³⁹ Special care was taken to avoid possible personal errors. The work was carried out by specially trained personnel

Red blood cell count Equipment: Pipets, hemocytometers and cover glasses certified by the U. S. National Bureau of Standards, microscopes with $\times 10$ oculars and $\times 43$ objectives, and 0.85 per cent sodium chloride solution used as diluting fluid and prepared with c.p. sodium chloride.

Method: The red blood cells contained in a surface of 0.20 sq. mm. (80 small squares) were counted. Both pipet dilutions and red cell counts were made in each case by two different persons. When the difference between the two counts exceeded 250,000 red cells per cm³, they were discarded and repeated. The final figure was obtained by averaging the two counts.

Hemoglobin determination Equipment: Two Leitz photocolormeters, one with cylindric cells, the other with square cells, filter number 401. The calibration curves of the colorimeters were obtained by determinations of the oxygen capacity in a Van Slyke volumetric apparatus and of the iron content according to Wong's method. Alternating current was used for one of the photocolormeters and direct for the other.

The blood was diluted to 0.5 per cent in 1.0 per cent solution of anhydrous sodium carbonate. Four readings with four new dilutions by two different technicians were made in each case. The final figures were the average of the eight readings, when the difference between those readings exceeded 0.50 Gm of hemoglobin the whole procedure was repeated.

Volume of packed red cells Equipment: Wintrobe hematocrit tubes, with an inside diameter of 3 mm and labeled from 0 to 100. Adequate pipets to fill the Wintrobe tubes.

Procedure: The hematocrits were spun at about 3,000 r.p.m. for 30 minutes. To assure a complete packing, they were spun 15 minutes more. Two hematocrits were determined with each specimen of blood and the figure reported in each case is the average of the two findings.

Sedimentation rate Equipment: Wintrobe tubes and specially leveled racks to keep the tubes in a vertical position.

Procedure: That described by Wintrobe.¹⁹ Only one reading was made at the end of an hour. Special care was taken to avoid the formation of air bubbles and the shaking of the tubes once placed in the rack.

Mean corpuscular diameter and mean corpuscular thickness Venous blood was obtained in 15 individuals, with the same previous conditions and the same careful techniques as the ones described before.

Procedure: The blood with the Paul and Heller anticoagulant was diluted in Simmel isotonic solution (8.2 Gm of NaCl, 0.02 Gm of KCl and 0.05 Gm of NaHCO₂) with a pH of 7.1. Only anhydric salts were used.

In each case 200 red cell diameters were read on a wet film, with Bausch & Lomb ocular micrometer and a precision screw.

Wet films were chosen to avoid shrinkage of the red cells.

For the mean corpuscular thickness the following formula was employed:

$$MCT = \frac{\text{Mean corpuscular volume}}{\pi \frac{(\text{Mean corpuscular diameter})^2}{2}}$$

RESULTS

The average red cell count was found to be 5,389,970 per cubic millimeter among the males and 5,014,160 among the females. The complete data are given in table 1. The distribution curves of the red blood cell counts are given in figures 1 and 2.

Hamre,¹⁴ Wintrobe³⁷ and most of the investigators agree that there is no difference in the number of erythrocytes between the two sexes during childhood, but that a significant difference appears upon reaching the age of puberty. In our series of cases the difference between the two sexes was significant. No difference was found in the number of red cells in relation to age among persons of the same sex (figure 3). No correlation was found between the number of erythrocytes and the socio-economic status. The influence of body surface on the number of erythrocytes is shown in figure 4.

The average amount of hemoglobin per 100 cc of blood was 17.74 Gm in males and 15.20 in females, no age variations being found. Distribution curves, averages, standard deviation, mean deviation, probable error and range are given in figures 5 and 6 as well as in table 1.

In the male group the volume of packed red cells averaged 51.23 cc, among the females, 45.43 cc (figures 7 and 8, table 1). The volume of packed red cells showed no relation to age or body surface (figures 9 and 10).

In the male group the following averages were also found: MCV, 95.85 cμ, MCH, 32.97 γγ, MCHC, 34.62 per cent, in the female group: MCV, 91.20 cμ,

FIG 1. Distribution curve of the number of erythrocytes in 100 healthy men The standard deviation is 329000 (3.29σ)

mean value nor its standard deviation, the volume of packed red cells did not bear out the assumption of anemia or polycythemia suggested by the red cell count alone, since it was found that a higher and a lower volume of packed red cells than normal corresponded to a lower and a higher cell count respectively (figs 17 and

18) Owing to this compensating mechanism, the amount of hemoglobin is kept within normal ranges

The determinations of the amount of hemoglobin, volume of packed red cells and number of red cells per cubic millimeter are also essential to appreciate the distribution of the hemoglobin in the erythrocytes

The mean corpuscular diameter found in the 15 individuals studied was 8.70μ

Sedimentation rate The average sedimentation rate found in the male group was 2.31 mm and it was 8.08 mm among females (table 1). There were no cases of foci of infection or of infectious diseases. The menses did not modify the sedimentation rate (figure 19). The sedimentation rates reported are uncorrected according to the volume of packed red cells.

DISCUSSION

In this series of cases it is apparent that the percentage volume of packed red cells and the amount of hemoglobin are slightly above the normal values obtained at sea level. As the red cell counts found are practically the same as those reported at sea level, the MCV and the MCH are higher than at low altitudes. The differences found require a study of the physiologic adaptation of the human body at different altitudes as well as a revision of the literature concerned with hematologic standards in different parts of the world.

As already stated, factors such as age, race, economic levels and most climatic conditions do not modify those standards in the adult.

In Mexico, Cabrera,⁴⁰ Izquierdo,⁴¹ and Ocaranza⁴² found a slightly diminished red blood cell count among natives of the Teotihuacan valley. A table of the most important investigations performed at sea level and low altitudes is presented in table 2. The investigations made in Mexico City and at other high altitudes are listed in table 3.

The physiologic adaptation of the human body at different altitudes has been studied by a number of workers since the last century. Bert,⁶² Viault,⁶³ Cordero,²³ Vergara Lope,²⁴ Sánchez Tagle,⁵⁸ Douglas et al.,⁶⁴ Fitzgerald,²⁷ Henderson and Haggard,⁶⁶ Barcroft et al.,²² Smith et al.,¹⁷ Ocaranza,⁶⁶ Izquierdo,²⁶ Hurtado,²⁸⁻²⁹ Licknatzky,¹⁸ Andresen and Mugrage,³⁰ Talbott and Dill.⁶¹

The transient hematologic modifications due to changes in atmospheric pressure are well known. During the first days of an ascent, an increase in the number of red cells has been found by Smith et al.,¹⁷ Licknatzky,¹⁸ Acton and Harvey,¹⁹ Horn-effer,²¹ Egger,⁶⁷ Koppe,⁶⁸ Wolfe,⁶⁹ Naegeli,⁷⁰ and others. When the ascent is rapid, there is an increase of 200,000 to 500,000 erythrocytes per cu. mm. in half an hour and of a million after 24 hours. Campbell and Hoagland⁷¹ estimate this increase as 5,000 red blood cells for each 1,000 feet. Meyer et al.⁷² and others⁷³ studied the erythrocyte increase in aviators and engineers. Grawits and Gruneberg,⁷⁴ Strohl and others⁷⁵ studied it in persons placed under low atmospheric pressures artificially obtained in special chambers. The modifications found in the latter study were similar to those found in Alpinists. The immediate increase in the red cell count when ascending is due to an increase in red blood cells secondary to the contraction of the spleen. This is proved by the fact that the increase in the red cell count does not appear in splenectomized animals when ascending. According to Zuntz⁷⁶ and Ocaranza⁷⁷ there is later an increase in hematopoietic activity, demonstrated directly by bone marrow biopsies and indirectly by the increase of reticulocytes and of bilirubin in the blood as well as by an increase in the whole blood volume, including both plasma and cells of animals and persons living under low atmospheric pressure. Peterson and Peterson⁷⁸ and Hurtado et al.²⁹ under the same conditions have also found a rise in the number of white blood cells.

It should be noted that most of these investigations have been performed in subjects exposed only temporarily to high altitudes, and furthermore, few of the investigators studied all the hematologic and organic changes. Very few of these investigations were made on natives or residents of high altitudes, but, together with ours, they have shown that the increase in the number of red cells is not the

only usual and constant feature of the long-standing hematological adaptation to high altitudes. Hurtado et al.²¹ among the inhabitants of Morococha, Oroya and Huancayo in the Peruvian Andes found

1. Only a slight increase in the number of erythrocytes compared with the figures found at sea level. In Oroya and Morococha at 3,730 and 4,540 meters respectively above sea level, the averages for red blood cell counts were 5,670,000 and 6,150,000 per c m.

2. Mean corpuscular hemoglobin averages of 33 and 33.9 γγ respectively in the same two places. These figures are slightly higher than those reported at sea level.

3. A marked increase in the volume of packed red cells and particularly in the mean corpuscular volume 54.1 and 95.2 c μ in Oroya and 59.9 and 97.5 c μ in Morococha.

The increase in the MCV was further confirmed by the finding of greater diameter, thickness and surface area of the red blood cells, as compared with those found at sea level (table 4). A high viscosity of the blood was also found. The blood cell variations mentioned and the slight increase in the serum proteins found by the same Peruvian investigators account for the increased viscosity.

There is a marked difference among the figures found in Mexico by different workers for the mean corpuscular diameter. Cordero reported it to be 5.9 μ, Gavilón, 7.26, and Ochoterena 7.49 (Quoted in reference 25.)

The mean corpuscular diameter of 8.7μ found in this study is the same one which has been found by Hurtado, considering that our investigation was done on wet films. A difference of 0.9μ exists between wet and dry films. These results are slightly above the normal known at sea level.

Andresen and Mugrage³⁰ in Denver, at an altitude of 1,520 meters, found a volume of packed red cells and a MCV of 48.35 cc and $93.3 \text{ c } \mu$ respectively for males and 43.22 and $89.2 \text{ c } \mu$ for females. These values are higher than those reported at sea level, with the exception of those found by Walters.³¹

These modifications of the red cells are probably due to the processes involved in a permanent adaptation to specific conditions found at high altitudes. It is a well known fact that a diminution in the atmospheric pressure and hence a decreased oxygen tension in the lungs is the only constant modification found at such altitudes. The interalveolar tension at sea level is 100, but it can be as low as 40 at high altitudes, and unless the organism compensates for the decrease of interalveolar tension by means of certain physiological processes of adaptation, blood oxygenation cannot be correctly fulfilled at high altitudes.

There is a close interrelationship of all human functions. If a change occurs in the environment, the organism will develop adequate anatomic and physiologic

TABLE 4

	MC Diameter	MC Thickness	MC Surface Area	Blood Viscosity
At sea level	7.48	2.09	137	4.64
In Oroya (3,750)	7.88	1.97	146	8.4
In Morococho (4,540)	7.74	2.08	145	

modifications of its various systems, even of those which are not in direct contact with it.

Physiologic observations show that organisms adapt themselves differently to the same external stimuli, if the length of time that the stimuli exert their action is different. At first, the organism resorts to all its mechanisms at hand, but later, if the external stimuli persist, it replaces those mechanisms with others that are slower to appear but which become permanent and thus more suitable to the needs created by the change.

After rapid ascents there is an increase in cardiac and respiratory rates as well as an increase of the heart output, demonstrated by Barcroft et al.²² These transitory changes disappear after a few days. Barcroft and his co-workers have also shown (Cerro del Mercado) that after a few weeks of residence at high altitudes there appears an increase in lung ventilation. According to Barcroft,²² Haldane,³² (p. 355) and the school of Copenhagen²² (p. 365) the increase in lung ventilation is due to the excitability of the respiratory centers, which in turn depends on the decrease of oxygen tension in the blood.

As a result of the hyperventilation there now appears a diminution in the CO_2 tension and an increase in the oxygen tension with a slight deviation of the blood

pH towards alkalinity. The difference between blood pH at high altitudes and blood pH at sea level is 0.02 to 0.06. Barcroft et al.²¹ found at Cerro del Mercado an oxygen consumption one fifth over that at sea level. Murray⁵² has shown that there exists a higher oxygen-combining capacity of hemoglobin in persons residing at high altitudes, owing to the increase in hemoglobin alkalinity.

A number of investigators—Douglas et al.,⁵³ Laquer,⁵⁰ Hurtado,²⁸ Hurtado et al.,²⁹ and Lozano and Solís⁵¹ among them—have found an increase in blood volume after some weeks of residence at high altitudes. The former used carbon monoxide in their determinations, the others, vital red and Evans blue. The averages found were 6 to 6.8 liters of whole blood and 2.6 liters of plasma, which correspond to 100 to 120 cc of whole blood and 36 to 46 cc of plasma per kilogram. At sea level the normal average of whole blood volume is 5 to 5.5 liters and of plasma 2.8 liters, that is, 85.5 cc of whole blood and 46 cc of plasma per kilogram. A comparison of these figures gives a clearer idea of the increase of total blood volume and especially of cell volume in residents of high altitudes.

Descriptions of special thoracic structures in natives of high regions can be found in the medical literature. Barcroft et al.²² made radiologic studies of the thorax of persons living in different places and found that the inhabitants at high altitudes have the largest thoracic expansion, the average height of each race having been considered.

Together with all these permanent physiologic and structural changes found in different systems, the red blood cell modifications described before are also seen. There are no phylogenetic observations opposed to the existence of macrocytosis at altitudes above sea level. Although many animals that live at high altitudes have smaller red cells than man's, there are others, like the eagle, which do not show that characteristic. On the other hand, it is true that the disproportion between volume and surface increases with the increase in size of a spherical figure, since they follow a different pattern of growth. This concept, which would explain a handicapped hemoglobin function, cannot be strictly applied to the erythrocyte, since this cell is not spherical but biconcave, and thus its volume is smaller than its surface as compared to the former. Moreover, it has never been proved that the hemoglobin is equally distributed throughout the erythrocyte. In fact, there are theories indicating that the hemoglobin is found specially at the periphery of the red cells (Burke⁸³ and others⁸⁴⁻⁸⁵). Hurtado²⁹ found the opposite, studying the relations of hemoglobin, red cell area and red cell volume. Perhaps the macrocytosis is due to the diminished oxygen tension in the blood.

The macrocytosis of the red blood cell together with the higher amount of hemoglobin per cell in comparison with the normocyte accounts, from a physiologic point of view, for only the slight hyperglobulia observed by some authors in residents of high altitudes. Owing to the physiologic macrocytosis, there is an increase of the total hemoglobin which favors the interchanges between the alveolar air and the erythrocytes, as well as between the erythrocyte and the body tissues.

The findings described in this paper, as well as the hypothesis⁸⁶ sustained in relation with the permanent hematologic adaptation of the organism to high altitudes,

indicate the necessity of further investigations that may or may not substantiate the above-mentioned concepts

CONCLUSIONS

1 Careful studies of the red blood cells in long-time residents of Mexico City (2,273 meters—7,457 ft) show a slight, although definite, increase in red cell count

2 The percentage volume of packed red blood cells, mean corpuscular diameter and the amount of hemoglobin per 100 cc of blood are higher in Mexico City than at sea level

3 There is an increase in the MCV and in the MCH as a result of the increase in the hematocrit and in the amount of hemoglobin without a definite correlated hyperglobulia

4 The MCHC corresponds to the normal values found by different authors at different altitudes

5 The relation between the hematologic standards studied and factors such as age, sex, diet and body build are in agreement with the findings of other workers

6 The changes mentioned in 2 and 3 have been observed by other investigators working under the same experimental conditions and they differ from those found among temporary residents of high altitudes

7 It is reasonable to assume that the increase of the MCV and that of the amount of hemoglobin are the result of a permanent physiologic process of adaptation to high altitudes, which appears only after a long residence

8 The existence of macrocytosis with increased corpuscular hemoglobin found above sea level possibly favors a better tissue oxygenation as well as other gaseous interchanges

ACKNOWLEDGMENTS

We wish to thank Dr Salvador Zubirán, Director of the Hospital de Enfermedades de la Nutrición where this work was carried out, and Dr Bernardo Sepulveda for their interest in the realization of this investigation. We are grateful also to the personnel of the Instituto Nacional de Cardiología, who helped us with the drawings and photography. We also thank Miss Isabel Escobar Barea, Q F B, and Dr Edmundo Rojas for their invaluable technical co-operation.

THE DEMONSTRATION AND CHARACTERIZATION OF THE ANTI-d AGGLUTININ AND ANTIGEN PREDICTED BY FISHER AND RACE

By SOL HABERMAN, PH D , JOSEPH M HILL, M D ,
BRUCE W EVERIST, M D , AND
J W DAVENPORT, JR , M D

WHEN the three-linked-genes theory of inheritance of the CDE/cde (Rh-Hr) blood antigens was proposed by Fisher and Race (1944)¹ some interesting correlations and remarkable predictions were made. On the basis of this theory, new blood antigens designated d and e were postulated in addition to the C, c, D and E which were then recognized. This is easily understood when it is noted that the red cell antigens C and c determined by their respective genes had a reciprocal relationship similar to the M and N antigens. In fact, Levine² had earlier described this relationship between C (Rh') and the antigen c (Hr') determined by his original Hr serum. Since D (Rh₀) and E (Rh'') had no such antithetical relationship to C and c or to each other, separate closely linked loci D and E were assigned to the genes determining these antigens. Because it seemed logical that D and E should likewise have antigens related to them in the same manner as c to C, Fisher predicted that the genes which he designated d and e, should be found.

Following these predictions, Mourant³ in 1945 reported the finding of a serum which detected an antigen having the specificity required for e. The e antigen having the same antithetical relation to E as c to C indicated that the genes E and e were allelomorphic (i.e. occurring interchangeably at the same locus in the chromosome). This serum, therefore, could be used to determine heterozygosity at the E locus. Although the Fisher-Race theory did not specifically predict more than two allelomorphic genes for each of the three loci, Callender, Race and Paykoc⁴ in 1946 discovered a third allelomorph at the C locus which they designated C*. This was followed by the finding of an additional allelomorph at the D locus by Stratton⁵ in 1946 designated as D^u. The finding of these two additional allelomorphs was quite compatible with modern concepts of genetics and constituted further evidence for the Fisher-Race theory.

During this period, unfortunately, the predicted anti-d serum remained undiscovered although it had become apparent that this serum would be the most important one for determining heterozygosity of husbands of iso-immunized women. At one time it was thought⁶ that the serum reported by Levine and Waller⁷ had a specificity suggestive of anti-d. However, this serum was proved to be identical in specificity to the St serum of Race and Taylor (anti-c). At the International Hematology and Rh Conference in Dallas, Texas, 1946, Diamond⁸ indicated that he

From The William Buchanan Blood Center, Baylor Hospital, Department of Clinical Pathology, Southwestern Medical College, Dallas, Texas, Department of Pediatrics, Louisiana State University, Unit of Charity Hospital, New Orleans, La., and Department of Intravenous Therapy, Serologic Research Laboratory, Southern Baptist Hospital, New Orleans, La.

had found a serum which contained weak antibodies against the d antigen in addition to anti-c

The present report is concerned with the demonstration of the anti-d agglutinin predicted by Fisher and proof of its specificity. This evidence was obtained by the following: (1) Differential agglutination of key red cells of known genotype, (2) quantitative hemolytic studies on such key erythrocytes and (3) determination of specificity of the agglutinin by its reaction with 100 random blood samples.

CASE REPORT

Female, age 26, quadroon, gave a history of having received several transfusions in 1938 while being treated for Paget's disease of the breast. No untoward reactions were recalled. Three previous pregnancies terminated in the delivery of normal infants in 1941, 1943 and 1945. On November 25, 1946 after an apparently normal pregnancy, a female infant weighing 5 lbs. 13 oz. and showing no gross abnormality was delivered at the Charity Hospital, New Orleans. However, typical erythroblastosis developed with marked icterus at eighteen hours. On the second day a hemoglobin determination showed 7.5 Gm. and

TABLE I

Blood From	Group	Antisera			Mother's serum	
		(D) (Rh ₀)	(C) (Rh')	(E) (Rh'')	Saline	Albumin
Father	O	+	—	—	+	+
Child 1	O	+	+	—	+	+
Child 2	A	+	+	—	+	+
Mother	A	+	+	—	—	—

Subsequently the baby's blood was tested

Baby	O	+	+	—	+	+
------	---	---	---	---	---	---

on the third day, 448 erythroblasts per 100 leukocytes were counted in the infant's blood. The first transfusion of 70 cc. Group O Rh negative blood was given on the day after birth. An additional four transfusions were given as required, the last on the tenth day consisting of 50 cc. of Rh positive blood. The baby was discharged on the twentieth day and has developed normally since that time.

Although the Rh positive erythroblastotic infant was initially given the usual Rh negative transfusions one of the authors (B. W. E.) noted that the mother was Rh positive and suggested the possibility of a rare intragroup isoimmunization. More complete serologic studies were undertaken in the Serologic Research Laboratory of the Southern Baptist Hospital. These studies by one of us (J. W. D.) as given in table 1, showed that the mother's erythrocytes were Group A and contained the C and D antigens but not the E. The father, of Group O, had D but no C or E in the red cells. The infant (and the other two children) gave Group O reactions and their red cells contained antigens D and C but not E. The mother's serum agglutinated the erythrocytes of the father and all three children. Tested against 22 random bloods (13 Rh Positive and 9 Rh Negative) the agglutinins of this serum exhibited no relationship to the M and N types. However, all Rh negative bloods were agglutinated and all but three of the Rh positive blood samples likewise showed agglutination. One additional positive blood showed agglutination in albumin but not in saline suspension. Substantial blood samples were collected from the patient in December 1946 and in March 1947. Serum from these collections were kept frozen at minus 20 C. During the period from December 1946 until May 1947 samples of serum from this case were submitted to many laboratories. All workers agreed that the serum contained an exceptionally strong anti-c (Hr') antibody and many suggested also the possibility of an anti-d antibody. Definite proof of the anti-d however was not forthcoming apparently due to a lack of rare test cells definitely known to be of genotypes negative for c but positive for d.

METHODS

Studies of the serum of this case begun at The William Buchanan Blood Center in May 1947 were designed to establish the identity of antibodies present by the methods described below. Two techniques were employed to demonstrate agglutination with the key test erythrocytes of known genotype (1) The classic test tube method⁹ using 2 per cent saline suspension of red cells and (2) the developing test¹⁰ employing the Coombs¹¹ antihuman globulin serum. Since the serum from the December bleeding appeared to contain two antibodies differing in reactivity as well as specificity, these two tests were especially useful. The antibody shown to have the specificity of anti-d reacted with both tests while the other antibody with the specificity characteristic of anti-c, reacted with the developing test, but not with the tube method using saline erythrocyte suspension.

The specificity of the two antibody components of the patient's serum was also determined by means of an estimation of their hemolytic action against selected erythrocytes. These studies of hemolytic activity of the serum were made by the quantitative hemolytic technic previously described.^{10, 12-14} This method established the net hemolysis resulting from the action of the antibodies present against the corresponding antigens of proper red cell suspensions under the standard optimum conditions over a period of forty-eight hours. Special advantage was taken of the observation made in earlier experiments^{12, 11} that the degree of hemolysis was related to the number of antigen antibody combinations available with a given cell and serum. The fact that the two antibodies were present in about equal strength made it possible to interpret the results very clearly.

Although the agglutination and hemolytic tests appeared to establish the specificity of the two antibodies in the patient's serum, it was considered desirable to further check the per cent specificity of the agglutinin component (anti-d) by agglutination of random samples to compare with the specificity of 65 per cent predicted by the calculations of Fisher.^{1, 15, 16} In so testing the erythrocytes from 100 random blood samples, the tube method using saline suspension of red cells was employed to bring out the activity of the agglutinin (anti-d) but not the crytagglutinin¹⁴ (anti-c) which was inactive against saline suspensions of erythrocytes. As a further precaution, these blood samples were subjected to parallel tests with anti C, C^x, c, D, E, e and P. These tests were performed with the Chown¹⁷ capillary technic because of its great economy of serum, especially important with such rare sera as anti-C^x and anti-c. All the sera so employed were known to be pure and free of other human erythrocyte antibodies.

One of the most important features of this study was the necessity of having available erythrocytes of suitable and definitely known antigenic composition. For example, the test cell of genotype CDe/Cde was of crucial importance in that it could be used to detect anti-d in the presence of the anti-c crytagglutinin found in this serum, without fear that the agglutination might be due to a weak anti-c agglutinin component. Since anti-d serum was not available prior to this case, it was necessary to do family studies to establish the absolute genotype particularly with reference to heterozygosity at the D locus. While individuals of this genotype should not be too rare (about 6.97 per 1000), they would be overlooked and considered as CDe/CDe unless studied in families to show segregation of the Cde chromosome. Fortunately, the genotype CDe/Cde was established in such a family while doing genetic studies with sub-type sera on the random blood samples from the pilot tubes of blood units collected for the Texas City disaster. Of course, the very much rarer (6.4 per 100,000) Cde/Cde could be detected serologically and used to good advantage but because of its rarity was not found in this large series of approximately 1000 blood samples.

RESULTS

The results of agglutination tests using key erythrocytes designed to differentiate Rh antibodies of different specificities are shown in table 2. The reactions with the

* *Crytagglutinoids*. Term proposed to designate those antibodies which neither agglutinate saline suspensions of erythrocytes nor give positive blocking tests (saturation of Rh antigen without agglutination in saline). Such antibodies may be detectable by such technics as the capillary, albumin and serum tests and are uniformly detected by the developing test using a sensitive anti-human globulin serum.

cells shown in this table give strong evidence that an agglutinin of specificity different from anti-C, c, C^w, D, E or e was contained in the serum of the patient reported in addition to the anti-c cryptagglutinoïd shown by the developing test. The positive reaction with the cell CDe Cde appears to rule in an anti-d agglutinin but does not entirely exclude the possibility of a rare antibody corresponding to an antigen determined by a rare or undiscovered allelomorphous gene of the Rh system or even

an unrelated blood antigen. However, the results from the agglutination studies of 100 random bloods shown in table 3 exclude this possibility. As further exclusion, comparisons with the Lutheran,⁴ Kell¹⁸ and Lewis¹⁹ antisera were made and no relationship was found. In this table it will be noted that 67 per cent of random bloods were agglutinated by the suspected anti-d agglutinin. This compares favorably with the 65 per cent predicted by Fisher and Race.¹⁵ However, if the data are examined further, it will be observed that the antigen determined by this serum (65-67 per

cent) has the same antithetical relation to D as M has to N. In other words each specimen is positive for D or d or both but never negative for both.

In figure 1, showing the results of hemolytic tests against CDe/cde and CDe/Cde cells, we obtain a clear confirmation of the presence of both anti-d and anti-c antibodies as well as demonstrating their hemolytic activities. Due to the almost

FIG. 1. ANTI-D SHOWN BY QUANTITATIVE HEMOLYTIC TECHNIC

identical titre of the anti-c and d, a unitary relationship between gene, antigen determined thereby, and amount of hemoglobin released by a given strength of antibody was established. This relationship has been previously reported,^{12 13 20 21} and will be dealt with in detail elsewhere.^{12 13 22}

DISCUSSION

The evidence presented in this paper is considered reasonably complete to establish the existence of an antibody having the characteristics predicted by Fisher and Race, namely anti-d. In order to substantiate the validity of such a new antibody and the antigen detected thereby, the following criteria may be considered essential: (1) the antiserum must be shown to give specific antigen-antibody reactions,

(2) it must be shown to differ from previously identified antibodies against human erythrocytes, (3) if more than one antibody is present in the serum it must be possible to recognize their separate effects (4) the percentage incidence (specificity) should be determined on random samples of human blood

The specific nature of the antigen antibody reaction for both components (anti-c and anti-d) was shown by several effects. First, by the use of the developing test the antibodies were shown to be adsorbed on erythrocytes containing the c and d antigens (cDE/cDE and CDc/CDc) and did not adsorb on erythrocytes lacking these antigens (CDc/CDc) as shown in table 2. Since the red cells are washed with saline in the developing test, only immune globulins specifically adsorbed remained on the red cell and therefore constituted a demonstration of the nature of the combination of the antibodies in the patient's serum and the corresponding antigens in the red cells. The specific antibody action of the anti-c and d components of the serum were further demonstrated by their hemolytic activity in the presence of complement as shown in figure 1. Fortunately, in this experiment through the choice of proper erythrocytes, the separate effects of the two antibodies could be observed because of the fact that they were of equivalent strength (titre). Thermal amplitude tests and studies of effect of dilutions of the serum which were done initially eliminated the possibility of panagglutinins, pseudo-agglutinins and cold agglutinins.

The results shown in table 2 indicate that the antibody component (cryptagglutinoïd) demonstrable only by the developing or albumin test was identical in specificity to anti-c. The agglutinin however as shown in tables 2 and 3 did not correspond to any of the available test sera, namely anti-C, C^u, c, D, E and e. Furthermore, additional tests run in parallel with the anti-Lutheran, anti-Kell and anti-Lewis serums showed no apparent correlation. Finally, comparative tests with anti-A, B and P, and the initial tests with anti-M and N done at the Southern Baptist Hospital ruled out these factors.

From the study of 100 random blood samples (table 3) a specificity of 67 per cent positive reactions was obtained. This compares with the 65 per cent specificity predicted from the calculations of Fisher. This agreement is the more significant when we note the antithetical relation between the reaction of anti-D and the agglutinin component of the serum herein described. These findings indicate allelismorphism of the gene determining the antigen (d) identified by this serum and the gene D.

It is believed that the evidence herein presented constitutes the demonstration and characterization of the d agglutinin and antigen.

THE Rh CHROMOSOME FREQUENCIES IN ENGLAND

Bj R R RACE, M R C S, L R C P, A E MOURANT, B M, B Ch, M A,
D Phil, SYLVIA D LAWLER, M B, B S, and RUTH SANGER, B Sc *

THIS paper reports the results of testing 1073 samples of blood, from English people, with the Rh antibodies anti-C, anti-C^u, anti-c, anti-D, anti-E and anti-e. To these are added another 927, tested with anti-C, anti-c, anti-D and anti-E, the results of which have been previously published.¹ Professor Fisher has used the total 2000 to estimate, by his method of maximum likelihood,² the frequencies of the Rh chromosomes in England, and has very kindly allowed us to make use of his results.

The discovery³ of the six elementary Rh antigens and their mutual relationships resulted from a study of the British work of 1943 on the isolation of the seven allelomorphs of the Rh gene. Fisher pointed out that the complex interactions of the four antibodies and seven allelomorphs† known at that time could be most simply understood by assuming that each allelomorph was built up from three elementary antigens, each of which could exist in two alternative or allelomorphic forms. These three pairs of allelomorphic antigens were called C and c, D and d, E and e. A chromosome could carry any combination of the three pairs, it might carry, for example, CDe or cde, etc. Seven of the eight theoretically possible combinations could be identified with the seven allelomorphs already known. The eighth combination, CdE, has still to be isolated, but there is a theoretical reason why it may be very rare.¹

As an individual has two sets of chromosomes, he has two Rh chromosomes and his genotype may be any combination, for example, CDe/cde. In this case his sex cells, which each contain only one chromosome of a pair, will carry either CDe or cde in equal numbers.

The four known Rh antibodies were thus renamed anti-C, anti-c, anti-D and anti-E. The antibodies anti-e and anti-d which the theory predicted were subsequently discovered,^{4, 5} and as a corollary the existence of the predicted antigens e and d were confirmed in a positive manner.

A third alternative to C and c, called C^u, was found⁶ in 1945. It has been isolated in the chromosome combination C^uDe and also C^ucde. Presumably the combinations C^uDE and C^udE exist although they may be very rare.

A third alternative to D and d, called D^u, was recognized⁷ in 1946, and it has been detected in the combinations CD^ue, cD^uE and cD^ue.

Twelve different Rh chromosomes have now been identified, they are CDe, cde, cDE, cDe, C^uDe, cdE, Cde, CDE, CD^ue, cD^uE, cD^ue, and C^ucde. These chromosomes can theoretically give rise to seventy-eight genotype combinations.

† An apology is needed for our use, in what follows, of the words *genes*, or allelomorphs, as synonymous with *antigens*. To avoid this is cumbersome, and it is possible that there may not be very much qualitative difference between blood group gene and blood group antigen.

TECHNIC OF THE GENOTYPE TESTS

Owing to the scarcity of the antisera, two of them being unique at the time of the work described, very small volumes are used, approximately 0.008 cc measured by Pasteur pipet marked with a wax pencil. The tubes used are 7 mm in external diameter and 50 mm long. They have a round bottom and are held in 50 hole wooden blocks. Such small volumes of fluid must be delivered nearly to the bottom of the tube.

One volume of serum and one volume of 2 per cent cell suspension in saline are incubated for at least two hours at 37°C. The contents are then gently pipetted onto a slide and read microscopically if agglutination is not obvious to the naked eye.

Although the antisera used were powerful examples of their kind, they were duplicated (excepting the two unique sera anti-C^w and anti-c). The duplication was performed partly as a check on the results but mainly in the hope of disclosing possible further allelomorphs of C, D, or E.

The 927 bloods of the first series¹ were tested with anti-C, anti-c, anti-D and anti-E and usually two examples of each serum were used.

In the examination of the second series of 1073 bloods, the following antisera were used

anti-C (anti-Rh')	one pure anti C and one mixture, anti-C plus anti-C ^w
anti-C ^w	one serum only
anti-c (anti-Hr)	two examples
anti-D (anti-Rh ₀)	one pure anti-D, one anti-D + anti-D ^u
anti-E (anti-Rh)	two examples
anti-e	one serum only

Anti-A or anti-B were usually removed from the sera by absorption with A₁B cells of the appropriate Rh genotype, as we had no A₁B cDE/cDE cells available, the anti-e serum was successfully treated with A₁B secretor saliva.

In order to avoid selection, we tested blood only from people whose Rh group had not previously been determined, and as far as possible blood of related people was excluded. The samples had, however, often been preselected for their ABO group. Counts on large sections of our results show complete independence of ABO group and Rh genotype. All the blood samples were taken by venipuncture and sent to us in the form of clotted blood.

RESULTS

Table 1 shows the result of our tests on 2000 blood samples. The first 927 were published in 1946¹ and are here reproduced because Fisher has made use of the combined information given by the two series in his calculation of the chromosome frequencies.

In the second series of 1073 bloods, it will be seen where the use of two further sera, anti-C^w and anti-e enabled distinctions to be made not possible in the first series. For example, C^wDe/CDe would have been included in the group CDe/CDe of the first series, and cDE/cDE would have been included with the more frequent genotype cDE/cde.

No attempt has been made to include the D^u distinctions in the tables. There were only two unequivocal examples of D^u in the 1073 bloods and these have been treated as ordinary D's. Owing to our possessing a pure anti-C^w, the recognition of the C^w antigen is easy and can be made in any combination, but there is as yet no pure anti-D^u serum, consequently D^u cells can be recognized only in the combination D^ud, not in D^uD. D^ud cells are agglutinated by some anti-D sera (anti-D + anti-D^u), and not by others (anti-D). This distinction being in part quantitative cannot be made with the certainty characteristic of the other antigen-antibody reactions of table 1.

Table 2 shows the chromosome frequencies calculated by Professor Fisher using

expected distribution. Columns 1 and 2 show the 36 genotypes, and their expected frequencies, that result from combinations of the 8 chromosomes of table 2. Those genotypes joined by brackets could not be distinguished serologically. Column 3 shows the frequencies expected of the 20 phenotypes distinguishable with the 6 sera used in the second series. Column 4 shows the absolute numbers expected in the 26 observational classes in the two series. Column 5 shows the numbers observed in these classes. The 6 observational classes additional to the 20 phenotypes arise because of the absence from the first series of 2 of the sera used in the second. For example, cDE/cdE and cDE/cde are distinct in the second series, but the 12 cDE of the first series were indistinguishable (in the absence of anti-e) and must therefore be placed in a separate group.

In the calculation of χ^2 shown in column 6, the 10 smaller classes have been pooled and are shown at the foot of the table.

GENETIC BASIS OF THE Rh GROUPS

Fisher suggested that the simplest genetic basis of the allelomorphous antigens, which he had demonstrated, would be a system of three closely linked genes. If the classic conception of a gene is adhered to, this seems to offer the only easy explanation of the observed facts. The alternative is the postulation of a new kind of gene, possessing three subgenes each capable of substitution by allelomorphs.

It seems wiser to conform to the traditional ideas, particularly since, as Fisher has pointed out,¹ there is some suggestive evidence for the occurrence of crossing over. This evidence will now be reviewed in the light of the results described in this paper. In the English population the common chromosomes are CDe, cde and cDE. The three resulting heterozygotes, CDe/cde, CDe/cDE and cDE/cde could give, if crossing over occurred, Cde and cDe, CDE and cDe, and cdE and cDe, respectively. If these rarer chromosome combinations did arise in this way, the

frequency of cDe would be expected to equal the combined frequencies of Cde , CDE and cdE . It will be seen from table 2 that $Cde + CDE + cdE = 2.41524$ per cent while $cDe = 2.56677$ per cent. In view of the sampling errors, this agreement is very close. The remaining combination CdE (Ry) would not be produced by a single cross-over from the common heterozygotes. It would require for its production a cross over occurring in a heterozygote involving a rarer chromosome, for example, CDe/cdE . This offers a rather satisfactory explanation of the apparent absence of CdE which is otherwise puzzling.

Fisher has suggested that the order within the chromosome is such that C lies between D and E . The reason for this view is that the frequency ratio of cdE to cDE/cde which represents a cross over between D and E , is considerably larger than the ratios of Cde to CDe/cde (cross over between C and E) and of CDE to CDe/cDE (cross over between C and E). These frequency ratios based on the results of the 2000 bloods are as follows

D—E	108	
C—D	030	} 051
C—E	021	

While this supports Fisher's view that the D — E distance is the greatest, yet the sum of the distances C — D and C — E does not correspond at all well with the total distance D — E . This can be explained by the fact that in the first series cdE was by chance too frequent, compared with a much larger series tested by Stratton⁹ with sera capable of detecting cdE . If the calculations are based only on the 1073 of the second series, the distances show remarkable agreement, thus

D—E		074
C—D	034	} 072
C—E	038	

The results obtained by Wiener, Zepeda, Sonn and Polivka⁸ in their tests on 99 Mexican Indians, lend support to the theory of crossing over as the cause of the rarer combinations in a population. The only frequent chromosomes in this population were CDe and cDE , and the only common heterozygote CDe/cDE . This, according to the theory, should result in the chromosomes CDE and cde having approximately equal frequencies in such a population. The chromosome frequencies calculated from this small sample were CDE 3.3 and cde 1.9.

It should be pointed out that no attempt is made to use the hypothesis of crossing over to explain the different racial distributions of the common chromosomes. It does however afford an explanation of the occurrence of the rarer chromosomes in a population in which the frequencies of the commoner combinations are already known.

SUMMARY

The results are reported of testing 1073 English bloods with the Rh antibodies anti- C , anti- C^w , anti- c , anti- D , anti- E and anti- e . The results of another series of 927 bloods, already published, are here reproduced. The total of 2000 bloods has

been used by Fisher to estimate, by his method of maximum likelihood, the Rh chromosome frequencies in England. The estimates are CDe 40.75 per cent, cDe 38.86 per cent, cDE 14.11 per cent, cDe 2.57 per cent, C^oDe 1.29 per cent, cdE 1.19 per cent, Cde 0.98 per cent, and CDE 0.24 per cent.

A brief account is given of the three pairs of alternative antigens shown by Fisher to be the basis of the Rh blood groups. Fisher's interpretation must now be considered as established beyond doubt. A possible genetic basis of these related antigens is discussed.

ACKNOWLEDGMENTS

We are deeply indebted to Professor Fisher for many reasons, but we should particularly like to acknowledge his kindness in allowing us to publish the results of his calculations of the chromosome frequencies.

For the antisera used in the investigations we are indebted to the following: Doctors E. F. Aubert, Sheila Callender, D. S. Dick, R. J. Drummond, Mr. I. Dunsford, Doctors A. J. McCall, Brenda Morrison, J. Murray, E. Wordley and R. A. Zeitlin.

We also thank Dr. H. F. Brewer of the London Red Cross Blood Donor Service, and Dr. J. F. Loutit of the National Transfusion Service, for providing us with large numbers of blood samples.

We also wish to acknowledge the assistance of Dr. Marjory N. McFarlane in the earlier part of this investigation.

DISTRIBUTION OF THE Rh TYPES IN SÃO PAULO (BRAZIL)

By F OTTENSOOSER, M D , P H D , C S LACAZ, M D , H C FERREIRA, M D,
AND O MELLONE, M D

THE FREQUENCY of Rh positives and Rh negatives in the white population of São Paulo¹⁻³ is about the same as that observed in the United States and England. In the present publication we deal specifically with the frequency of the eight types of the Rh factor found in São Paulo.

The anti-Rh₀ serum (85 per cent) was selected by ourselves in São Paulo, but both anti-Rh' (70 per cent) and anti-Rh'' (30 per cent) were obtained in New York (Blood Donor Service). We used the technic prescribed by Levine⁴ incubating from 30 to 60 minutes in a water bath, centrifugation, and reading the re-

TABLE I

Classes	Anti Rh serum				Anti Rh serum			
	Rh ₀	Rh'	Rh''	Types	Rh ₀	Rh'	Rh''	Types
W	—	—	—	Rh neg	+	—	—	Rh ₀
U	—	+	—	Rh'	+	+	—	Rh ₁ (Rh' ₀)
V	—	—	+	Rh''	+	—	+	Rh (Rh'' ₀)
UV	—	+	+	Rh'Rh''	+	+	+	Rh ₁ Rh. (Rh' ₀ Rh'' ₀)

cell sediment macroscopically and microscopically. That human anti-Rh agglutinins act better at 37 C than at lower temperatures was shown by Levine, Burnham and Katzin.⁵

Using these three anti-Rh sera we could identify eight types of the Rh factor, as shown in the scheme by Wiener, Sonn and Belkin,⁶ which has been used throughout the United States (table 1).

A very different nomenclature has been accepted in England,⁷⁻¹⁰ which makes the subject somewhat more complicated. Until an international nomenclature¹¹ has been adopted we intend to continue using the nomenclature proposed by Wiener.¹²

Table 2 presents the geographic distribution of Rh types among various populations, including our results in São Paulo (Brazil). It is quite obvious that the frequency of the different types varies considerably according to race. In our statistics a few Negroes and mulattoes were omitted. Unfortunately the anti Rh serum of Levine⁵ was not available to us.

From Hospital das Clinicas, University of São Paulo, Brazil

The distribution of the Rh types among the white population of São Paulo (Brazil) is

Rh negative (cde)	15.2 %	Rh ₀ (cDe)	5.8 %
Rh' (Cde)	1.4 %	Rh ₁ (CDe)	55.2 %
Rh'' (cdE)	0.7 %	Rh ₂ (cDE)	10.1 %
Rh' Rh'' (CdE)	0 %	Rh ₁ Rh ₂ (CDE)	11.6 %

TABLE 2

Population	Number of determinations	Frequency of the types of Rh factor							
		Rh-	Rh ₁	Rh	Rh ₁ Rh ₂	Rh ₀	Rh'	Rh''	Rh Rh''
New York { a b c	1 000	12.9	54.1	12.8	16.4	2.6	0.9	0.3	0
	818	13.5	55.6	15.8	12.0	1.7	1.1	0.3	0
	2,438	14.5	52.5	15.7	13.1	2.4	1.1	0.7	0.02
Negroes (New York)	223	8.1	20.2	22.4	5.4	41.2	2.7	0	0
Great Britain	927	14.8	54.9	12.2	13.7	2.5	0.7	1.3	0
Australia	350	14.9	54.0	12.6	16.5	0.6	0.9	0.5	0
Asiatic Indians	156	7.1	70.5	5.1	12.8	1.9	2.6	0	0
Chinese	132	1.5	60.6	3.0	34.1	0.8	0	0	0
Mexican Indians	98	0	48.0	9.2	41.8	1.0	0	0	0
Japanese { a b	150	1.3	37.4	13.3	47.3	0	0	0	0.7
	180	0.6	51.7	8.3	39.4	0	0	0	0
Filipinos	100	0	87.0	2.0	11.0	0	0	0	0
Indonesians	100	0	75.0	2	22	0	0	0	1
Present note Brazil (S Paulo)	138	15.2	55.2	10.1	11.6	5.8	1.4	0.7	0

The frequency of Rh types in São Paulo agrees with the North American, British, French¹¹ and Australian observations in white population, Rh negative (15.2 per cent) being slightly above the average because of the inclusion of some recognized Rh negative blood donors.

The type Rh₁ is by far the most frequent (55.2 per cent). The frequency for Rh₀ (5.8 per cent) is slightly higher, and for Rh₂ (10.1 per cent) is lower, than in the other statistics.

EDITORIAL

FOLIC ACID, PERNICIOUS ANEMIA AND PENDULUMS

FOLIC acid, pteroyl glutamic acid (PGA), was heralded in 1946 as one of the "wonder drugs" of the year.¹ A few mg of the drug given orally was often found sufficient to cause a dramatic remission in typical cases of pernicious anemia. In such related conditions as sprue,² pernicious anemia of pregnancy,³ "tropical" macrocytic anemia⁴ and the like, the drug seemed to have an even greater therapeutic effect than did liver extract. The two chief questions which followed in the wake of the initial successes were, (1) how did it work so effectively even when given by mouth, and (2) would it prevent the development of neurologic manifestations?

The physiologic mechanisms by which PGA is effective are still quite obscure, but there can be no doubt that the various studies which have followed its introduction have illuminated certain aspects of the pathogenetic mechanisms in pernicious anemia.⁵ Of greatest importance to the clinician however is whether or not PGA will in and of itself adequately protect the patient with pernicious anemia against the development of progressive involvement of the central nervous system, granted that other aspects of the deficiency state (bone-marrow, blood, gastrointestinal disturbances) are kept under control. During 1947 it became apparent that PGA often failed to prevent the development or progression of neurologic symptoms and that the signs of spinal cord involvement might develop explosively in patients taking the drug.⁶

Towards the end of 1947 an editorial entitled, "A Warning Regarding The Use of Folic Acid," appeared in the New England Journal of Medicine⁷ which not only cast doubt on the ability of PGA to prevent neurologic involvement but even raised the possibility that the material might have a more or less directly harmful effect on central nervous system tissue. The editorial closed with the following statements: "sufficient evidence has accumulated to justify a warning that synthetic pteroyl glutamic acid (folic acid) should not be used in the treatment of pernicious anemia. In view of the reports of folic acid induced neurologic lesions in sprue this restriction should probably also apply to other nutritional macrocytic anemias. Consequently the use of folic acid as a therapeutic agent appears to offer *no new benefit but only risk to the patient*" (Italics ours.) So striking has been the impact of this editorial that many physicians have discontinued completely the use of PGA in their practice.

The above editorial stemmed in part from the work of Ross⁸ and his collaborators, based on the treatment of 22 cases of pernicious anemia with folic acid.⁸ In 7 cases, neurologic relapses developed, and in 4 there was progression of combined system degeneration. Neurologic relapse occurred with considerable suddenness and progressed rapidly in several patients, especially in those receiving large (10 to 25 mg) doses. This suggested the ingenious possibility that PGA, particularly when given in large doses, might contribute to dysfunction of the central nervous system by interfering with its metabolism of L(+) glutamic acid.

Some observations had already been made indicating that both the naturally occurring l(+) and d (-) glutamic acid are involved in nerve tissue metabolism (quoted by Ross⁹) Glutamic acid is one of the constituents of the folic acid molecule, and Ross points out that its position in the molecule suggests that it may enter into competition with the naturally occurring l(+) glutamic acid and thus interfere with normal nerve metabolism Ross implies that this interference might explain the greater frequency of neurologic relapse in patients receiving large doses of folic acid and the progression of neurologic disease in others

From the available evidence, it appears probable that PGA cannot be relied upon as the sole agent in the treatment of pernicious anemia since its use may not only prevent injury to the central nervous system but may actually be attended with harmful effects to nerve tissue Liver extract must therefore remain, at least for the present, the sheet anchor in the treatment of Addisonian pernicious anemia This does not exclude the possibility that PGA may *also* be useful (1) as an adjuvant to liver extract therapy and (2) as a more specific substance than liver extract in certain conditions related to Addisonian pernicious anemia but not identical with it

As regards the first possibility, Meyer,⁶ for example, holds to the opinion that small doses of PGA, combined with liver extract injections, induce better remissions, both hematologic and neurologic, than either substance alone Ross et al.⁹ also state "These observations suggest that a combination of orally administered folic acid and parenterally injected liver extract may maintain a better hematologic status than either substance alone" In my own experience, small doses of folic acid, e g , 5 mg per day, have proved useful in the maintenance therapy of pernicious anemia, in conjunction with injections of liver extract at two to four week intervals This combination has seemed desirable on physiologic grounds since (1) an active therapeutic agent is given daily to supply a chronic deficiency state and (2) the patient receives at stated periods a deposit of a known and time tested material, i e , liver extract Under this regimen, all the patients treated have stated that their feeling of vitality is considerably improved, in addition, their red cell counts have tended to be higher than on liver extract alone No evidence of neurologic relapse has occurred As an adjuvant to liver extract therapy, PGA gives one the impression as being of distinct value

Has the drug a specific action in some cases which is not shared by liver extract? In 2 of our cases of neurologic pernicious anemia,¹⁰ the administration of PGA was followed by a distinct neurologic remission, after prolonged liver extract therapy had proved ineffective In one of these cases, a reticulocytosis of 8.2 per cent developed at a red cell level of approximately 4.0 million per cu mm, whereas previously, liver extract therapy had resulted in only a 2.4 per cent response at a level of 3.8 million These findings seem to indicate that at least for these particular patients, folic acid was more nearly the required specific substance than was liver extract

In non-Addisonian pernicious anemia (that is, in conditions such as sprue, the macrocytic or pernicious anemia of pregnancy, the so-called tropical macrocytic anemia, and the megaloblastic macrocytic anemia of infancy) the efficacy of liver

extract, particularly of the refined type, leaves much to be desired. Lucy Wills,⁴ for example, writes that "the liver principle is actively curative in pernicious anemia but does not seem to be the missing factor in nutritional macrocytic anemia." This "missing factor"¹¹ was alluded to by Watson and Castle as the 'Wills' factor' in an article dealing with the therapeutic inefficiency of parenteral liver extract in certain cases of atypical pernicious anemia. It is possible that the missing factor is PGA, especially since various workers have demonstrated that this material often results in a more marked therapeutic effect than does liver extract in cases of atypical pernicious anemia. Results in these cases suggest that the chemical acts specifically on certain enzyme systems that are not appreciably affected by liver extract. They also indicate that there may be different types of pernicious anemia brought about by varying mechanisms and even by different deficiencies.

The exact place of PGA in the armamentarium of therapy still remains to be clearly defined. That it is harmful to central nervous system tissue has not been conclusively demonstrated. Certainly the evidence at hand hardly justifies the categorical statements in the above mentioned editorial that the drug "should not be used in the treatment of pernicious anemia" and other nutritional macrocytic anemias and that its use appears to offer "only risk to the patient." These gloomy forebodings are hardly borne out by the results of many workers, particularly in the field of atypical pernicious anemia. Suarez,⁸ for example, states that in the treatment of over 100 cases of sprue, not only has he seen no evidence of harm neurologically but the patients do better than with liver extract. Spies and co-workers¹² have recently shown that patients with nutritional macrocytic anemia can be maintained for as long as two years with folic acid as the sole medication without the development of subacute combined degeneration of the spinal cord.

Pendulums have a way of swinging too far in one or the other direction before they finally settle down. The 'PGA' pendulum, it would seem, has now swung far over on the reactionary side, as opposed to the enthusiastic left swing of 1946. This is perhaps only natural, in view of the disappointing results attending its use as the *sole* medication in typical pernicious anemia. However, when the exact nature of the liver extract factor has been defined, and when we know more about the specific enzyme systems concerned in the development of pernicious anemia, the pendulum should settle down, and PGA will then find its rightful place in the treatment of certain aspects of the pernicious anemia family of deficiency diseases.

HEMOGLOBIN, METHEMOGLOBIN AND BILIRUBIN METABOLISM

SPECIFIC OXYGEN AFFINITY OF HEMOGLOBIN IN ELASMobrANCHS AND TURTLES. *F. H. McCutcheon*. From School of Veterinary Medicine, University of Pennsylvania. *J. Cell & Comp. Physiol.* 29: 333-344, 1947.

Knowledge that fetal goat's hemoglobin has a higher affinity for oxygen than maternal hemoglobin has led to further investigations along developmental and comparative lines. In the present study, various elasmobranchs and turtles were obtained in the adult, fetal and embryonic forms. In general, sharks had a higher loading capacity and a lower unloading capacity for oxygen than the rays. Unlike other animals, the fetal ray had an affinity for oxygen like that of the adult. Lack of material did not permit a study of the more embryonic stages. In the turtles, the terrestrial forms had a higher affinity than the aquatic forms. In the development of turtles, no changes in oxygen affinity occur until after the embryos hatch. By the end of the second year the adult type of hemoglobin is established. These and similar results may be correlated with ontogenetic, phylogenetic, ecologic and physiologic factors.

O P J

CYANOSIS IN INFANTS IN RURAL AREAS (WELL-WATER METHAEMOGLOBINAEMIA). *H. Medow, W. C. Guest, and M. Victor*. From the Department of Paediatrics, University of Manitoba and the Department of Medicine, Winnipeg General Hospital, Winnipeg, Manitoba, Canada. *M. A. J.* 56: 505-508, 1947.

One certain and one probable case of methemoglobinemia are reported in infants whose formulae included well water containing from 110 to 250 parts of nitrate per million. The upper limit of safe nitrate content is given as 10 parts per million. In both cases cyanosis disappeared without treatment within one or two days after the use of well water was discontinued.

Four similar reports, including one fatal case, in the literature are cited, all cases occurring in infants during the first two months of life. It is suggested that the determining factors are body weight, nitrate content of well water and amount of water ingested. The incidence of well-water methemoglobinemia would, therefore, be highest in areas where farm sanitation is poor, wells poorly constructed and where dried milk mixtures are extensively used.

The efficacy of methylene blue and ascorbic acid in treating methemoglobinemia is briefly discussed. Prompt recognition of the condition is most important, since spontaneous recovery follows when use of contaminated well water is abandoned, provided the methemoglobin content of the blood has not risen too high.

L E Y

THE ROLE OF PYRIDINE NUCLEOTIDES IN THE REDUCTION OF METHEMOGLOBIN. *H. R. Gutmann, B. J. Jandorf, and O. Bodansky*. From the Biochemistry Section, Medical Division, Army Chemical Center, Edgewood Arsenal, Maryland. *J. Biol. Chem.* 169: 145-152, 1947.

The early studies of Warburg on the mechanism of erythrocyte methemoglobin reconversion are extended by these authors. Methylene blue was used as a part of the system because of its known ability to accelerate the reaction. While glucose functions as a substrate in the intact erythrocyte, hexose diphos-

phate or lactate are necessary in hemolysates. Methemoglobin reversion occurred in the hemolysate when nicotinamide was employed to suppress pyridine nucleotide hydrolysis. The essential substrates for the reduction of methemoglobin in these experiments appeared to be reduced DPN and phosphorylated glucose or lactate. These observations, unfortunately, do not throw any light on the one clinical state in which the cell reconversion mechanism does not function—congenital methemoglobinemia. This would suggest that the reconversion system is more complex than herein described.

C. A. F.

SIGNIFICATION BIOLOGIQUE DES CORPUSCULES DE HEINZ. LEUR RAPPORT AVEC LES VERDOGLOBINES (Biologic significance of the Heinz corpuscles, their relations with the verdoglobins.) *A. Gajdos and G. Tipreț*. Travail de la clinique médicale de l'Hôtel-Dieu (Paris). *Sang* 18: 35-43, 1947.

In 1890, Heinz was the first to notice the appearance of basophilic corpuscles in the red cells during phenylhydrazin intoxication. These corpuscles are stained by supravital staining, but in contrast to reticulocyte granulations, they disappear when later stained by a panoptic method (May-Grünwald Giemsa). Several hemolytic poisons, and some sulfonamide drugs bring on the corpuscles, in vivo as well as in vitro. Their chemical nature and their biologic significance have been the subjects of numerous researches. Some think they are due to methemoglobin, others that they are related to verdoglobins (intermediary substances between hemoglobin and bile pigments).

The experiments of A. Gajdos and G. Tipreț bring new arguments for the close relations between Heinz corpuscles and verdoglobins. They show that all substances able to transform hemoglobin into verdoglobin induce Heinz corpuscles in vivo and in vitro, in particular ascorbic acid. Moreover, the same factors are acting (pH, temperature, speed of formation) for both verdoglobin and Heinz corpuscles. Thus, these corpuscles seem to represent an alteration of the hemoglobin in the red cells by hemolytic poisons.

J. P. S.

ICTERUS NEONATORUM. ITS INCIDENCE AND CAUSE. *L. Findlay, G. Higgins, and M. W. Stanier*. From the Department of Biochemistry, Radcliffe Infirmary, Oxford, England. *Arch. Dis. Childhood* 22: 65-74, 1947.

The authors studied the incidence of physiologic icterus in the newborn and attempted to decide whether it is due chiefly to hemolysis or to some other factor, such as hypofunction of the liver. They found first that up to 81 per cent of newborn infants had a plasma bilirubin in excess of 1 mg. per cent (i.e., laboratory icterus), although much fewer (e.g., 18 per cent of one group) had clinical jaundice. At two weeks of age, all infants studied had levels of 1 mg. per cent or less. The level of neonatal plasma bilirubin roughly paralleled that of the cord blood, but there was not a strict correlation, nor was there a correlation between the plasma bilirubin and the maturity of the fetus. Jaundice, however, was more likely to occur the more premature the baby.

pregnancy	jaundice
32-35 weeks	100% of subjects
36-37	65%

40 (term)	47%

It is generally taught that physiologic icterus is the result of hemolysis, which is said to cause the fall in hemoglobin and red cell count from the prenatal to neonatal levels. Against this concept the authors adduce the following data:

1. The most rapid fall in hemoglobin and red count occurs in the second week of life, whereas the hyperbilirubinemia occurs largely in the first week. The fall in blood values continues for months, long after the jaundice is gone. (*L. Findlay Arch. Dis. Childhood* 21: 195, 1946.)
2. The rate of fall of hemoglobin was found to be the same in jaundiced and in nonjaundiced infants.
3. None of the usual concomitants of hemolysis (reticulocytosis, normoblastosis) occurred postnatally, whereas fetal umbilical blood was found regularly to contain increased reticulocytes and normoblasts.
4. The erythrocytes of fetal blood showed increased fragility to hypotonic solutions, those of neonatal blood showed decreased fragility. (*Arch. Dis. Childhood* 20: 64, 1945.)

The authors believe that neonatal physiologic icterus is the result of immaturity of function of the liver which like many other organs is relatively immature at birth. In utero, they postulate, the fetus's bilirubin is excreted largely by way of the maternal placenta, so that not till birth does the liver begin to excrete bilirubin. Attempts to study neonatal liver function gave inconclusive results but more bilirubin was found in the feces of nonjaundiced than of jaundiced infants.

HEMOGLOBINEMIA AND HEMOGLOBINURIA

A NOTION STUDIES OF HEMOLYTIC PAROXYSMAL (COLD) HEMOGLOBINURIA. *P. F. Hagle, W. H. Zinkman and L. A. Sellers*. From the Department of Medicine, Johns Hopkins University, Baltimore, Maryland. *Am J Med* 34: 346, 1947.

A preliminary report is made of studies carried out on the blood of a syphilitic patient with paroxysmal cold hemoglobinuria. It was shown that saturation of the patient's blood with carbon dioxide produced hemolysis of the erythrocytes, an effect which was not dependent on a reduction of the pH of the serum (as is the case in paroxysmal nocturnal hemoglobinuria). This hemolysis was dependent on the presence of a hemolysin in the patient's serum.

Inhibition of the carbonic anhydrase of the erythrocytes with cyanide or with sulfanilamide blocked the hemolytic action of chilling. This blockage was due to inhibition and not to destruction of the carbonic anhydrase.

Microscopic observation of erythrocytes being hemolyzed by the patient's serum showed that these cells underwent considerable swelling and morphologic changes just prior to lysis.

J F R

RAYNAUD'S PHENOMENON, WITH PAROXYSMAL HEMOGLOBINURIA, CAUSED BY COLD HAEMAGGLUTINATION. *C. H. Whittle, A. Lyell, and M. Getman*. *Proc Roy Soc Med* 40: 500-502, 1947.

The chief point of interest in this patient with a five year story of anemia and a two year story of episodes of blueness, tingling, and numbness of the hands on exposure to the cold, is the extraordinarily high titer of the autoagglutinin circulating in the blood serum. The patient had no physical abnormalities except after chilling, when bluish red blotches appeared over the fingers, hands, and tips of nose and ears. The blood studies showed a persistent macrocytic anemia with reticulocytosis and thrombocytosis, and normoblastic hyperplasia of the bone marrow. The titer of autoagglutinin was 1:2,000,000 at ice-box temperature, and the red cells were very fragile to mechanical trauma when kept at low temperatures. Actual rupture of the red cells was visible *in vivo* under the capillary microscope.

S E

MARCH HEMOGLOBINURIA. *A. M. Bell*. From Alvinston, Ontario. *Canad M A J* 57: 43-46, 1947.

The case reported is that of an apparently normal 18 year old soldier who for three months exhibited hemoglobinemia, hemoglobinuria, albuminuria and abdominal distress after walking for periods as short as thirty minutes. For at least part of the three months the appearance of symptoms seemed to depend upon the presence of food in the upper digestive tract. Further study of this phenomenon was prevented by spontaneous remission. A brief review of march and other types of paroxysmal hemoglobinuria is given and the association of albuminuria with hemoglobinuria is discussed.

L E Y

PREPARATION OF HEMOGLOBIN SOLUTIONS FOR INTRAVENOUS INFUSION. *P. B. Hamilton, L. E. Farr, A. Hiller and D. D. Van Slyke*. From the U. S. Navy Research Unit at the Hospital of The Rockefeller Institute for Medical Research, New York. *J. Exper. Med.* 86: 455-463, 1947.

A method is described for preparation of sterile, nonpyrogenic solutions of oxyhemoglobin which have the approximate protein content and electrolyte composition of plasma. The procedure involves precipitation of stroma by adding 0.1 N HCl to laked red cells and removal of excess potassium by treatment with sodium zeolite.

The authors report that large volumes of solution can be rapidly prepared with 95 to 98 per cent of the hemoglobin in active form capable of combining with oxygen. Solutions stored at 4 C. showed no

conversion of hemoglobin to methemoglobin over a period of two and a half months, but a small and variable conversion was detected over a six month period

LEY

PREPARATION OF DRIED HEMOGLOBIN WITHOUT LOSS OF ACTIVITY *L E Farr, A Hiller and D D Van Slyke*
From the U S Navy Research Unit at the Hospital of The Rockefeller Institute for Medical Research,
New York *J Exper Med* 86 465-475, 1947

The methods used for freezing, drying and preserving plasma in vacuo were successfully applied to hemoglobin solutions, but only after hemoglobin was deoxygenated to prevent formation of methemoglobin during the drying process. It was found that deoxygenated hemoglobin dried and preserved in vacuo retained all its oxygen-binding capacity for 180 days when stored at temperatures from 4 to 30 C., for 92 days at 38 C and for 7 days at 56 C. Dried deoxygenated hemoglobin was partly converted to methemoglobin by even momentary contact with oxygen, but it was stable when dissolved in water before being exposed to air and could be stored for months at 4 C, in contact with air, without significant loss of activity. The dried hemoglobin had a foam structure which caused it to dissolve immediately upon contact with water.

Deoxygenation was accomplished by repeated shaking of hemoglobin solutions under diminished pressure. All but traces of oxygen were removed by alternately de-gassing the solutions and saturating them with oxygen-free nitrogen. It is pointed out, however, that after completion of this work, Pennell, Smith and Werkheiser reported a procedure for deoxygenation by action of enzymes in laked cells after addition of nicotinic acid and glucose. This method is considered better adapted to large scale preparations.

LEY

RENAL EFFECTS OF HEMOGLOBIN INFUSIONS IN DOGS IN HEMORRHAGIC SHOCK *P B Hamilton, A Hiller and D D Van Slyke*
From the U S Navy Research Unit at the Hospital of The Rockefeller Institute for Medical Research, New York *J Exper Med* 86 477-487, 1947

Dogs were bled, 50 cc per kilo body weight, and the blood withdrawn was quickly replaced by equal volumes of 0.9 per cent NaCl solution, heparinized dog plasma, or 7 per cent oxyhemoglobin or methemoglobin solution. The effects of more prolonged hemorrhagic shock were not studied. When the blood was not replaced, oliguria or anuria developed and the urea clearance was depressed for several hours after bleeding, but renal function returned to normal within twenty-four hours. Infusion of 0.9 per cent NaCl solution or plasma promptly relieved the oliguria and elevated the urea clearance. Injection of oxyhemoglobin solution also relieved oliguria promptly, but in some cases there followed a period of three to five days in which urea clearance was depressed to about 25 per cent of normal and plasma urea nitrogen was moderately elevated. The clearance then returned to normal during the next five or six days. No histologic observations are reported.

When acidosis was produced before bleeding by giving NH_4Cl , the results after infusion of plasma or hemoglobin were unchanged, but since hemorrhage itself caused nearly as much acidosis as the NH_4Cl , acidosis was not excluded as a factor in these experiments.

It was shown that methemoglobin was rapidly converted into active hemoglobin after injection, and that there was no significant difference between infused oxyhemoglobin and methemoglobin either in effect on renal function or in rates of disappearance from circulation and excretion in the urine.

The authors conclude that, although the immediate effects of hemoglobin solutions are favorable in treating posthemorrhagic shock in dogs, the subsequent transitory depression of urea clearance indicates sufficient possibility of renal damage to prevent recommending the use of such solutions as blood substitutes.

LEY

RENAL DAMAGE FOLLOWING INTRAVASCULAR HEMOLYSIS *E L Burwell, T D Kinney, and C A Finch*
From the Department of Medicine and Pathology, Peter Bent Brigham Hospital and Department of Pathology, Harvard Medical School, Boston, Massachusetts *New England J Med* 237 657-665, 1947

A case of massive intravascular hemolysis following a therapeutic abortion is presented and the management of the subsequent anuria is discussed in detail. The etiology of the hemolysis was attributed to

either more of a chemical or indirectly way of the uterus or by its direct reaction to an orally injected drug. Dr. Hetschelt has called the attention of the author to the article by Hill on Post-abortal and Puerperal Gas Gangrene (J. Clin. & Expt. Med. 1943, 1944) and the similarity of this case to the reported cases of hemolysis due to *Brucella abortus*.

The recovery of the renal function as shown by renal function test is a surprise in the death of the patient three months later with acute hepatic failure. The final autopsic findings as found to consist of only minimal scarring. The hepatic pathology is a pathogenesis of the pathobiochemical response and its treatment are reviewed.

C A I

THE PATHOGENESIS OF THE RENAL INJURY PRODUCED BY THE DOGS BY HEMOLYSIS OF METHEMOGLOBIN
H. I. Hines, H. B. Burt, N. K. Obermayer, R. A. Zerk, From the Department of Pathology, Yale University School of Medicine, New Haven, Conn. J. Exp. Med. 63: 553-556, 1947

Severe and persistent impairment of renal function was produced in dogs by extreme intravascular hemolysis due to the administration of injection of large amount of dog hemoglobin and methemoglobin. Methemoglobin caused more severe renal injury than equal amount of oxhemoglobin. In oliguric dogs, azotemia and reduction of creatinine clearance followed injection of methemoglobin in amounts resulting in plasma concentrations of 1 Gm. per 100 cc., whereas much higher concentrations were tolerated by dogs with greater urine output. Acidosis produced by administration of 0.1 N hydrochloric acid appeared to have less effect than oliguria in the production of renal damage after injections of methemoglobin. In acidotic dogs, the pH of the urine to comply with the onset of hemoglobinuria, sometimes from approximately 7.2 to 7.0, but no explanation of this change is given.

Kidneys of the animals were examined by the ferrocyanide histochemical technique to determine whether the renal tubules were functionally obstructed. In addition, casts were teased out of frozen sections dissolved in buffer solutions and the absorption spectra and solubilities of their pigments were determined.

Material filling the lumina of the tubules was found to be chiefly methemoglobin in concentrated solution of gel-like consistency. No evidence of formation of pigments such as hemochromogen or hematin, insoluble at the pH of the urine, was found. Obstruction to the flow of urine through the tubules appeared to be an important factor in early reduction of renal function and was attributed to increased viscosity of tubular contents. It is worthy of note, however, that the concentrations of hemoglobin and methemoglobin produced in the plasma in these experiments were for the most part considerably in excess of those encountered clinically. The mechanism of cast formation under these conditions is not yet clear.

Necrosis of proximal convoluted tubule cells was found as a late lesion and was deemed a contributing factor in the persistent depression of renal function. Following disappearance of most of the intratubular pigment, many collapsed tubules lined with hemosiderin-filled cells were found and were considered to represent nonfunctioning nephrons.

Direct measurements with a T-tube cannula inserted into the renal vein in two animals failed to reveal any reduction of renal blood flow following injection of methemoglobin in amounts sufficient to produce renal injury. It should be pointed out, however, that the method here employed might fail to measure a reduction in effective renal blood flow, if such occurred, due to diversion of flow from cortex to medulla by recently discovered shunting mechanisms.

IRON METABOLISM

THE PATHOGENESIS OF CYTOSIDEROSIS (HEMOCHROMATOSIS) AS EVIDENCED IN MALNOURISHED AFRICANS
J. Gillman and T. Gillman. From the Department of Anatomy, Medical School, University of the Witwatersrand, Johannesburg, South Africa. Gastroenterology 8: 19-23, 1947

Based on numerous histochemical studies of liver biopsy material and tissues obtained postmortem from nutritionally deficient African natives, many of whom presented clinical and pathologic evidences of hemochromatosis, a theory is proposed by the authors regarding the sequence of events operative in the pathogenesis of that disease. Initially, as a complication of malnutrition, commonly pellagra, there occurs a degradation of intracellular iron compounds, possibly cytochrome or catalase. During this stage of the process a striking porphyrin-like fluorescence is demonstrable on examination of liver tissue, it is

presumed that other tissues are likewise involved in this process of deterioration. Iron liberated with the liver is excreted into the bile, then promptly and completely reabsorbed into the intestinal mucosa. The cells lining the intestinal tract, similarly affected by the underlying metabolic disorder, become laden with iron. Iron accumulates in the lymphocytes of the tunica propria and subsequently enters the lymphatic circulation, chains of mesenteric lymph nodes becoming progressively pigmented. Eventually sufficient iron becomes absorbed into and distributed by the systemic circulation to effect a generalized siderosis of the entire reticulo-endothelial system, including the Kupffer cells, which now serve as an additional source of iron delivered to the upper abdominal lymph glands, already pigmented from iron-containing lymph derived from the liver itself. In severe cases these glands draining the small intestine, stomach, pancreas and liver become extensively involved. Successful arrest of the process necessarily involves an attack on the fundamental disorder of intracellular metabolism, which is believed to be secondary to a nutritional deficiency.

C.P.E.

HAEMOSIDEROSIS PULMONUM. *P. Haussen* From the Medical Department of the City Hospital of Bergen, Bergen, Norway. *Acta Paediatr.* 34: 103-111, 1947.

A case of this unusual syndrome was diagnosed clinically from the appearance of the pulmonary roentgen picture and the hematologic status. This was characterized by the mixture of sideropenic and hemolytic symptoms that is typical for the malady. The hemoglobin responded well to iron therapy. There was noted a constant reticulocytosis, urobilinuria and periodically increased serum bilirubin. Of special interest is the demonstration of large amounts of hemosiderin in microscopic sections of the patient's sputum. Another finding that may possibly be of importance for the understanding of the disease in the future was a sarcoid-like structure found in an excised cervical lymph gland. No autopsy was performed but the clinical diagnosis was quite convincing. It is probable that this syndrome is sometimes overlooked and should be diagnosed more frequently.

J.W.

STUDIES ON FREE ERYTHROCYTE PROTOPORPHYRIN, PLASMA COPPER, AND PLASMA IRON IN NORMAL AND IN PYRIDOXINE-DEFICIENT SWINE. *G. E. Cartwright and M. M. Wintrobe* From the Department of Medicine, University of Utah School of Medicine, Salt Lake City, Utah. *J. Biol. Chem.* 172: 557-565, 1948.

This is an extension of previous studies by these authors on the anemia produced by pyridoxine deficiency in swine. Normal values of erythrocyte protoporphyrin in swine were found to be $118 \pm 43 \gamma$ per 100 cc, serum copper $206 \pm 26.3 \gamma$ per cent, and serum iron $169 \pm 38.8 \gamma$ per cent. In pyridoxine deficiency, protoporphyrin was reduced to an average of $47 \pm 13.6 \gamma$. Copper was reduced to $160 \pm 38.8 \gamma$ per cent while serum iron showed an increase to $408 \pm 166.6 \gamma$ per cent. Urinary coproporphyrin was not altered. Following intravenous administration of pyridoxal and pyridoxamine, serum iron dropped to normal limits within twenty-four hours, and erythrocyte protoporphyrin rose over several days to above normal limits.

The authors suggest that in view of the reduced free erythrocyte protoporphyrin, the fundamental disturbance in erythropoiesis may be a failure to synthesize protoporphyrin. The elevation of serum iron and tissue hemosiderosis is a natural sequence of this block in hemesynthesis.

These investigations are the first to suggest such a defect in protoporphyrin metabolism as a cause of anemia. Investigations along this line are warranted in Cooley's anemia which has certain similarities to the anemia of pyridoxine deficient swine.

C.A.F.

REDUCTION OF IRON BY FOODS IN ARTIFICIAL GASTRIC DIGESTION. *E. R. Kirsch, O. Bergheim, J. Kleinberg, and S. James* From the Department of Biological Chemistry, College of Medicine, and the Department of Chemistry, College of Pharmacy, University of Illinois, Chicago, Illinois. *J. Biol. Chem.* 171: 687-694, 1947.

A method is described of measuring ferrous and ferric iron in the presence of each other. Under conditions simulating gastric digestion, the degree of reduction and binding by various foods and biologic materials was tested. The reduction of iron varied with different foods from 0 to 98 per cent. Ascorbic acid and proteins were felt to be in part responsible for this reduction.

Recent studies have indicated that dietary factors are important in determining iron absorption. Since there is some evidence that iron must be in the ferrous form for absorption to occur, this reduction capacity of the diet may be a determining factor

C A F

VARIATIONS DE LA SIDEREMIE ET DE LA CUPREMIE AU COURS DE LA REGENERATION DES ANEMIES PAR LA METHIONINE (Variations in the Blood Iron and Copper Concentrations Found in the Course of Anemias Treated with Methionine) *A Lafontaine and A Gajdos* *Sang* 18 242-246, 1947

The authors describe 4 cases of human anemia treated with 2 Gm methionine daily, in which the amount of serum iron and copper were estimated (Iron estimated by the method of Heilmeyer and Plotner, modified by Lederer and De Mouschalt, copper estimated by the method of Callan and Henderson, modified by Briskas) In all 4 cases, the amounts of serum iron and copper increased considerably at the beginning of the treatment, despite a diet poor in these elements. The increase of serum iron is more important than that of serum copper. While the anemia regresses, the copper, and above all the serum iron, decreases. It seems, therefore, that methionine aids the mobilization of iron and copper. It would be interesting to give iron with methionine therapeutically.

J P S

LEUCOPENIA AND AGRANULOCYTOSIS

THE EFFECT OF TRIMETHYLOXAZOLIDINE DIONE (TRIDIONE) ON THE BLOOD *J P Davis and W G Lennox*
From the Department of Neurology, Harvard Medical School and The Children's and Infants' Hospital, Boston, Mass. *J Pediat* 31 24-33, 1947

Periodic hematologic examinations of 127 patients receiving tridione demonstrated, as the only alteration of possible serious significance, the gradual development of a definite neutropenia in 63 per cent, the neutrophil counts in this group falling to values between 600 and 1600 per cubic millimeter. An additional 7 per cent exhibited a mild neutrophilic depression, counts descending below 2500 per cubic millimeter. The total leukocyte count was relatively unaffected, due to a concomitant absolute lymphocytosis. The occurrence of granulopenia was unrelated to dosage of the drug, or to the therapeutic schedule employed, no premonitory or accompanying clinical manifestations or hematologic abnormalities were observed, in no instance was its onset abrupt, or its progression rapid. Restoration of a normal granulocyte count promptly and invariably followed discontinuance of the drug. Therapy was resumed in 3 cases without recurrence of neutropenia. It is emphasized that, whereas drugs with this type of molecular structure may be potential bone marrow depressants, the administration of tridione may be safely controlled and the development of a marked or irreversible neutropenia forestalled by conducting monthly hematologic examinations which should always include a leukocyte differential, as well as total white cell count.

C P E

AGRANULOCYTOSIS AND HEPATOCELLULAR JAUNDICE TOXIC REACTIONS FOLLOWING PROPYLTHIOURACIL THERAPY *H J Livingston and S F Livingston* Brooklyn, N Y *J A M A* 135 422-425, 1947

The 68 year old hyperthyroid patient who forms the subject of this report developed sudden acute neutropenia (agranulocytosis) after the previously uneventful administration of some 13,400 mg of propylthiouracil in a period of ten weeks. The blood showed 1,000 white cells with no granulocytes at all, and granulocytes were virtually absent from the marrow puncture. About the same time, however, a non-hemolytic jaundice supervened, attributed to hepatocellular damage caused by the propylthiouracil. Treatment consisted of penicillin, streptomycin, amino acids, liver extract, vitamin injections, and blood transfusion, and improvement gradually occurred. The thyrotoxicosis remained unchanged and required subsequent thyroidectomy.

It is impossible to evaluate this curious case from the published article, in which no tables were included because of lack of space. The neutropenia is amenable to explanation on the basis of known damage to granulocytopoiesis in the marrow, which has been well demonstrated in the case of various drugs, including thiouracil, and has been reported for half a dozen cases with propylthiouracil. The occurrence of hepatic involvement must be very rare or even unique, and the question of its etiology remains unexplained from the data presented.

S E

LEUKOPENIA FOLLOWING THE USE OF PROPYLTHIOURACIL *W J Eisenrenger and J M Steele* From the New York University Division of the Lenox Hill Hospital, New York J A M A 135 510-11, 1947

The authors report a patient of 65 with hyperthyroidism, who developed a leukopenia and neutropenia (white cells 3,400, neutrophils, 40 per cent) after administration of some 36 grams of thiouracil in a period of five months. Cessation of drug therapy was followed by prompt return of the leukocyte and neutrophil values to normal, but relapse in the hyperthyroidism occurred within two months. The patient was therefore put on propylthiouracil, 50 mg three times a day, and later 75 mg daily. There was no effect on the blood counts, but the thyrotoxicosis remained uncontrolled, and the dose of propylthiouracil was raised to 200 mg daily. This increase in dosage was followed by a rapid fall of white count to 2,100 per cu mm, with 22 per cent neutrophils. This drug, too, was therefore stopped, and the count returned to normal values. Thyroidectomy was subsequently used to control the hyperthyroidism.

According to the authors, of some 471 cases treated with the drug this is the seventh case in the literature of leukopenia due to propylthiouracil.

S E

THE RH FACTOR AND ERYTHROBLASTOSIS FOETALIS

ERYTHROBLASTOSIS FOETALIS OR HAEMOLYTIC DISEASE OF THE NEWBORN *L K Diamond* From the Children's and Infants' Hospitals and the Harvard Medical School, Boston, Mass. Proc Roy Soc Med 40 546-550, 1947

This is the substance of a lecture delivered by Diamond in England in May 1947. Several points covered in this review are of interest.

1. About 13 per cent of all marriages involve an Rh negative woman and an Rh positive man, but only one in 150 of all deliveries results in an infant with erythroblastosis foetalis. In other words, less than one susceptible woman in 20 is sensitized by pregnancy alone, whereas a single transfusion of Rh positive blood, followed by subsequent pregnancy, in an Rh negative woman, increases the chances that the child will be erythroblastotic from 5 per cent to over 50 per cent.

2. The results of treatment of affected infants over a period of some twenty years are reviewed. During fifteen years in which the only treatment was transfusion of compatible blood, usually from the baby's father (i.e., Rh positive), the mortality, including stillbirths, was 40 per cent. During three years in which treatment consisted of multiple small transfusions with Rh negative blood, the mortality was 30 per cent. In the period of 1944 to 1946, when early delivery in affected cases was combined with Rh negative transfusions after delivery, the mortality was 20 per cent. The newest technique, combining early delivery with careful studies at birth and, when indicated, exsanguination-transfusion of affected infants, resulted in a mortality of about 10 per cent in the first 50 cases. Of those that recovered, most responded to the single procedure of exsanguination-transfusion, and only a few needed a subsequent small transfusion in the third week of life.

3. Diamond gives flexible indications for exsanguination-transfusion. The procedure is indicated (a) when the mother has Rh antibodies in the serum, and the infant has clinical erythroblastosis foetalis, (b) when the mother has Rh antibodies in the serum, the infant has no symptoms at birth, but cord blood shows the baby to be Rh positive and his serum to have Rh antibodies. If the infant looks good and, although Rh positive, has no free antibody by suitable tests, no therapy is attempted at birth, in most of this group, no treatment became necessary, although a few such infants subsequently required a single transfusion of blood.

The experiences of Diamond are in keeping with generally held ideas concerning the mechanisms of erythroblastosis foetalis.

S E.

HAEMOLYTIC DISEASE OF THE NEWBORN IN SOUTH AFRICAN NATIVES. REPORT OF THREE CASES *A Zentgraf* From the South African Institute for Medical Research, Johannesburg. South African M J 21 794-796, 1947

The 3 cases of erythroblastosis foetalis cited in this report are presumably the first to be described among South African natives. It is emphasized that only 5 per cent of the natives are Rh negative and that only 18 per cent of Bantu bloods react with anti-C (anti-Rh¹) serum as compared with 70 per cent among Europeans.

peans It is extremely rare, moreover, to encounter native bloods which react with anti-E (anti-Rh'') serum (30 per cent among Europeans)

All of the 3 cases reported occurred in infants born of Rh positive mothers, and in each case incomplete antibodies were present while abnormal agglutinins were absent In the first case the baby's type was CDE (Rh₁Rh₊) and the mother's type was CDe (Rh₁), incomplete antibodies against CDE (Rh'') were found in the maternal serum—a finding of rarity even among Europeans In the second case the baby's type was CDe (Rh₁), the mother's Cde (Rh'), anti-D (Rh₀) incomplete antibodies were present In the third case the baby's type was CDe (Rh₁), the mother's CDe (Rh₀), and incomplete anti-C (Rh') antibodies were detected

L E Y

THE INTELLIGENCE QUOTIENT IN CASES OF RHEUS INCOMPATIBILITY *M Creak Arch Dis Childhood* 22 181-182, 1947

Forty-three unselected cases of erythroblastosis fetalis who survived were studied for intellectual development by means of Gesell's development quotient (D Q) and standard intelligent quotients (I Q) It was found that 5 children who had gross neurologic involvement consistent with kernicterus, all had low D Q and low I Q In all, jaundice and anemia had been present after birth Only two other children had slightly low D Q and I Q On the other hand, 7 other children with slight physical abnormalities not suggestive of kernicterus, had normal D Q and I Q, and in 2 of these, jaundice had been extremely severe

These results suggested that severe mental defects in such patients is closely associated with the physical characteristics of neurologic damage In the absence of such damage due to kernicterus, the mentality is perfectly normal Erythroblastosis fetalis in itself, in other words, has no particular relationship to impaired intellectual development, unless the latter is due directly to brain damage attributable to kernicterus

S.E

DETERMINATION OF ANTI-RH ANTIBODY IN INFANTS WITH ERYTHROBLASTOSIS FETALIS *W E Wheeler and M L L Scholl From the Department of Pediatrics, Ohio State University College of Medicine, and the Children's Hospital, Columbus, Ohio Am J Dis Child* 74 274-282, 1947

A superior method for liberation and demonstration of both complete and incomplete anti-Rh antibodies attached to erythrocytes of babies with erythroblastosis is described Washed packed red cells from the infant are divided into two equal portions, one of which is resuspended in 3 volumes of saline, the other in a similar amount of a 20 per cent solution of bovine albumin Both portions are heated at 45 to 50 C for 30 to 40 minutes, then centrifuged rapidly at the same temperature and the supernatant fluids tested with Rh₁, Rh₂ and Rh negative cells of the same OAB group In 10 of 11 cases, the albumin supernate gave a positive conglutination test, but all of the saline supernates failed to produce agglutination In 6 cases, however, Rh positive cells incubated in the saline supernates became sensitized as demonstrated by their agglutination when anti-human-serum rabbit serum was added

It is emphasized that these procedures establish the specificity of the antibody attached to the baby's cells, whereas the Coombs, Mourant and Race (CMR) test with rabbit serum, when carried out by itself, merely demonstrates the presence or absence of cell-bound globulin The ease with which Rh antibodies are separated from cells by heat suggests to the authors that the antibodies have low avidity They offer this as an explanation for the puzzling situation present at birth in which there may be found free antigen in agglutinable red cells, free antibody in the baby's serum and antibody combined with antigen in the red cells It is further suggested that after an Rh positive cell is damaged, Rh antibody may be released *in vivo* to attack fresh Rh positive cells introduced into the circulation, and that antibody may not be bound to fresh cells permanently The importance of these considerations in exchange transfusions and in the transfusion of Rh positive cells to erythroblastotic infants is stressed

L E Y

STUDIES ON THE CONGLUTINATION REACTION, WITH SPECIAL REFERENCE TO THE NATURE OF CONGLUTININ *A S Wiener, J G Hurst, and E B Sonn-Gordon From the Serological Laboratory of the Office of the Chief Medical Examiner of the City of New York J Exper Med* 86 267-284, 1947

The nature of conglutinin was explored by adding plasma and plasma constituents singly and in combination to Rh₁ and Rh₂ cells sensitized in respective tubes with serial dilutions of Rh antisera containing incomplete antibodies. Supernatant fluid was removed as completely as possible from the cells before conglutinin was added.

It was found that dilution of oxalated human plasma with more than an equal volume of saline destroys its ability to produce conglutination of cells sensitized by univalent antibody. Plasma showed greater conglutinating activity than serum, presumably due to the presence of fibrinogen, which the authors consider an important component of the colloidal complex of proteins making up conglutinin. Heating at 56 C. for 30 minutes weakened slightly the activity of plasma by causing precipitation of fibrinogen, but similar treatment of serum improved its activity slightly.

Although there was little variation in conglutinin activity of sera from different normal adults, fetal plasma and serum yielded much lower titers. The rapid increase in conglutinin content of the blood after birth is correlated with the abrupt onset of icterus gravis. The use of whole citrated blood in exchange transfusion of an erythroblastotic baby caused a rise in total plasma proteins and conglutinating activity, whereas replacement of transfused plasma with saline eliminated this unfavorable change in the infant's plasma.

Although 25 per cent human albumin solution yielded titers only half as high as plasma, a mixture of 1 part albumin with 3 parts plasma produced a fourfold increase in titer of the plasma. Addition of more or less than this optimal amount of albumin resulted in lower titers. Albumin solutions of less than 12.5 per cent and immune globulin solutions of less than 4.6 per cent concentration had little conglutinin activity, but mixtures of these dilute solutions in optimal proportions showed activity greater than that of plasma. On the basis of these observations it is emphasized that intensity of conglutination does not depend merely on the total protein content of the medium of suspension. It is further suggested that there may be substances in normal plasma which tend to maintain albumin and globulin in molecular dispersion, and that fractionation may render albumin and globulin less hydrophilic, thus increasing their tendency to form colloidal aggregates.

LEY

MALIGNANT LYMPHOMA

LA DIAGNOSI CITOLOGICA DEL GRANULOMA MALIGNO PER PUNTURA MIDOLLARE, SPLENICA E GHIANDOLARE (Cytologic diagnosis of Hodgkin's disease by bone marrow, splenic and lymph node aspiration) L. Battistoni and F. Perazzini. From the Istituto di clinica medica generale e terapia medica della università di Bologna. *Hematologica* 30: 89-112, 1947.

The authors studied 7 cases of Hodgkin's disease by means of organ punctures and biopsies. They found in bone marrow punctures, an increase in plasma cells which were frequently atypical, but only occasionally noted Sternberg cells. In the splenic punctures there was an inversion of the normal ratio lymphocytes/granulocytes as a result of increase in the granulocytes, and Sternberg cells were often noted. In lymph node punctures, Sternberg cells were found in all cases and there was a striking cellular polymorphism, with granulocytes (neutrophils and eosinophils), lymphocytes and reticular cells.

In other words, of these three procedures, lymph node puncture was the easiest and the safest way to insure a diagnosis of Hodgkin's disease.

JPS

LYMPHOMAS AND LEUKEMIAS. THE VALUE OF EARLY DIAGNOSIS AND TREATMENT. L. F. Grater. From Memorial Hospital, New York. *J. A. M. A.* 136: 244-249, 1948.

This article is part of a series on early diagnosis and treatment of various forms of cancer. The author summarizes present principles of treatment of the lymphomatous disorders. A few highlights are:

1. Any inflammatory lymphadenopathy which persists for three weeks should be considered malignant until disproven by thorough investigation, including biopsy.
2. The treatment of choice for Hodgkin's disease or lymphosarcoma is intensive x-ray therapy to the involved areas. It is emphasized that the minimum doses just sufficient to cause regression of masses are not adequate therapy, but much larger doses—probably to the limit of skin tolerance—are indicated. (Specific schedules are given.)

3 The treatment of choice for chronic leukemias is also x-ray

4 The nitrogen mustards are of palliative value in certain disorders, notably generalized Hodgkin's disease. Radioactive isotopes are of palliative value, notably radioactive phosphorus or sodium in chronic leukemia. Urethane may be effective in some chronic leukemias, but inconstantly (25 to 33 per cent of cases). None of these agents is considered the treatment of choice.

5 Certain early cases of Hodgkin's disease, which seem to be localized, may be cured by complete local excision followed by intensive postoperative irradiation, or, perhaps, by intensive local irradiation alone.

S E

RECENT ADVANCES IN TREATMENT OF LYMPHOMAS, LEUKEMIAS AND ALLIED DISORDERS. L F Craver. From the Memorial Hospital, New York. *Bull New York Acad Med* 24: 3-25, 1948.

The author summarizes his own experience at the Memorial Hospital and that of other recent observers in a well organized review. Particular emphasis is placed on (1) improvement in palliative results in Hodgkin's disease, lymphosarcoma and chronic lymphatic leukemia by early detection of local lesions and treatment with roentgen irradiation, (2) use of nitrogen mustards in patients with generalized Hodgkin's disease, (3) use of P₃₂ in polycythemia and in chronic myeloid and lymphatic leukemia with minimal enlargement of spleen, liver and nodes. The limited application of urethane in some cases of leukemia and of stilbamidine in multiple myeloma is briefly discussed.

In looking to the future, the cure of some cases of Hodgkin's disease and lymphosarcoma is considered a possibility. If these diseases have a unicentric origin, sufficiently early obliterative roentgen therapy, or even radical surgery might prove curative, in the author's opinion. Considerable hope is also held for more specific attack on these disorders by means of further modifications in radioactive isotope therapy and by discovery of more effective chemical agents.

DISCUSSION. TREATMENT OF THE LYMPHADENOPATHIES. R B Scott, M J Stewart, E L Cohen, D W Smitbers, and J D N Nabarro. *Proc Roy Soc Med* 40: 617-622, 1947.

Several points of interest are included in this informal discussion of the treatment of the lymphomatous diseases. The generally accepted doctrine that, on the whole, treatment does not influence duration of life, although it may affect comfort and economic usefulness during life, is supported by comparative data. Comparison of patients with Hodgkin's disease treated with x-ray (1939) and without x-ray (1923) showed no statistical difference in survival times, although improvement of symptoms following x-ray is well known. A similar result is noted in the leukemias and reticulososes. Scott points out that surgical excision of a localized group of nodes involved in Hodgkin's disease may allow permanent cure, and mentions 3 such personal cases. Isolated instances of such result are well known, although the procedure is accepted with hesitation by most.

It is of interest that splenectomy is recommended (by Scott) in the occasional selected case of Hodgkin's disease or leukemia in whom symptomatic hemolytic anemia or symptomatic thrombocytopenia supervenes. The principle that splenectomy is not necessarily contraindicated once the diagnosis of lymphomatous splenomegaly has been made, but that the operation, by affording relief, especially from a hemolytic process superimposed on the underlying disorder, is becoming increasingly recognized as good medical practice in properly selected cases.

S E

THE CLINICAL AND PATHOLOGIC EFFECTS OF THE NITROGEN AND SULFUR MUSTARDS IN LABORATORY ANIMALS. I Gratz, D A Karnofsky, V B Jager, B Krichesky and H W Smith. From the Departments of Physiology and Pathology, New York University College of Medicine. *Am J Path* 24: 1-47, 1948.

The effects of various nitrogen and sulfur mustards were investigated in albino mice, albino rats and New Zealand rabbits. Whenever possible, the effect of these compounds in other species was presented. In general, leukopenia was the most distinctive feature of the intoxication. Bone marrow reacted by showing initial degenerative changes followed by a rapid depletion of all hematopoietic cells. Weights of the spleens, thymuses and lymph nodes decreased markedly. These changes were reflected histologi-

cally by a loss of follicles in lymph nodes, an atrophy of malpighian corpuscles in the spleens and a shrinkage of the thymic cortex followed by involution. The effects of different routes of administration were discussed as well as the effects on other systems and tissues

O.P.J

THE EFFECTS OF β, β' -DICHLORODIETHYL-METHYLAMINE HYDROCHLORIDE ON THE BLOOD FORMING TISSUE
G. R. Cameron, F. C. Courtice and R. P. Jones. From the Experimental Station, Porton, Wilts, England.
J. Path. & Bact. 59: 425-435, 1947

A nitrogen mustard in the form of its hydrochloride was administered to rabbits and dogs for the purpose of studying its effect on the blood and hematopoietic organs. Doses given either intravenously or subcutaneously produced similar results. There was a generalized damage to the blood forming tissue but they did not all respond in the same manner nor to the same degree. Germinal centers of the lymph nodes and the spleen showed necrosis as early as three to six hours after administration of the drug. This was reflected in the blood by a lymphopenia and in the thoracic duct lymph by a decreased output. Damage to the bone marrow was reflected by a granulocytopenia following an initial increase. This granulocytopenia could be maintained by repeated doses of the drug. Since red corpuscles have a longer life than granulocytes in the circulating blood, anemia was produced only after repeated doses of the nitrogen mustard. Experimental anemias were produced in treated and untreated animals to determine the extent of bone marrow damage. The reticulocyte response was delayed in treated animals but it rose quite rapidly after the drug was discontinued. The action of this nitrogen mustard on the hematopoietic organs is very rapid and the recovery from it equally so.

O.P.J

NITROGEN MUSTARD AS A THERAPEUTIC AGENT FOR HODGKIN'S DISEASE, LYMPHOSARCOMA, AND LEUKEMIA
M. M. Wintrube, C. M. Huguley, Jr., M. T. McLennan, and L. P. de C. Lima. From the Department of Medicine, University of Utah School of Medicine, Salt Lake City, Utah. Ann. Int. Med. 27: 529-540, 1947

Seventy-seven patients were treated with di(B-chlorethyl) methylamine hydrochloride, employing in most cases a dose of 0.1 mg./kilo repeated four to six times. In Hodgkin's disease along with general improvement and decrease in size of the involved lymphoid tissue, there was a striking alleviation of fever. Pruritus was variably affected, dependent on the general response to treatment. Response was considered to be good in 61 per cent of 28 cases, and remission occurred in several patients considered to be x-ray resistant. In lymphosarcoma, response was good in 4 of 11 patients and in chronic leukemia one-third of the cases responded well. Results in acute leukemia were generally unsatisfactory although mention is made that small doses of mustard were very effective in bone pain. The authors observed a consistent reduction in both granulocytes and lymphocytes following therapy, but in only one case did they encounter the clinical picture of agranulocytosis. The red count and platelet levels were variably affected.

C.A.F

NITROGEN MUSTARD THERAPY IN CUTANEOUS BLASTOMATOUS DISEASE. E. D. Osborne, J. W. Jordan, F. C. Hoak, and F. J. Pschirer. From the University of Buffalo School of Medicine, Buffalo, New York.
J. A. M. A. 135: 1123-1128 (1947)

This report concerns the effect of the nitrogen mustards in 4 patients with lymphomatous disorders of the skin, and 1 patient with diffuse lupus erythematosus. Two patients with mycosis fungoides showed prompt and dramatic improvement in both signs and symptoms, but rapid relapse with progression (and death in 1 case) occurred. One patient with lymphosarcoma showed dissolution of skin lesions, lymph nodes, and abdominal masses, but died within two weeks with progressive severe leukopenia. It is of interest that no gross or microscopic evidences for lymphosarcoma were present at autopsy, although biopsy before treatment showed definite lymphosarcoma. In a patient with combined Kaposi's sarcoma and Hodgkin's disease, the nitrogen mustard therapy had no effect. In a patient with chronic diffuse lupus erythematosus, who had had no response to x-ray therapy, the use of nitrogen mustard was followed within four days by virtual disappearance of the eruption. The patient continued to improve,

although a few areas of chronic discoid lupus erythematosus appeared on the face and neck within three months

Most dramatic in the patients' responses was relief of the severe, stubborn itching present in mycosis fungoides and in the patient with lupus. The results here presented duplicate, in general, other observations of the response of lymphomatous disorders to the nitrogen mustards. The authors emphasize that they do not advocate the general use of these agents in nonmalignant conditions such as disseminated lupus.

S E

EFFECTS OF URETHANE IN THE TREATMENT OF LEUKEMIA AND METASTATIC MALIGNANT TUMORS *J S Hirschboeck, M C F Lindert, J Chase, and T L Calvy* From Marquette University School of Medicine, Milwaukee County Hospital, Milwaukee, and Veterans Hospital, Wood, Wisconsin *J A M A* 136 90-95, 1948

The results of the treatment of 25 patients with leukemia, and 8 patients with malignant neoplasm, with urethane are summarized. The drug was most effective in producing remission in patients with chronic myelogenous leukemia. Its effect was inconstant in chronic lymphatic leukemia. It was of no value in the acute leukemias, or in the patients with carcinoma or sarcoma. These results are in line with previous investigations of the effects of urethane in these disorders. The drug is recommended as an adjunct form of therapy in selected cases of leukemia, and not as a general substitute for x-ray therapy in these diseases.

S E

LYMPHOBLASTOMA. AN EVALUATION OF THE DIFFERENCES IN SENSITIVITY TO X-RAY IRRADIATION OF DIFFERENT TYPES, AND ITS APPLICATION TO A QUANTITATIVE THERAPEUTIC TEST *W L Palazzo* From the Radiation Therapy Department, Bellevue Hospital, New York *Radiology* 48 484-492, 1947

In this report the author attempts to classify various lymphomata according to their response to x-ray therapy, and proposes a therapeutic test with x-rays. His list places giant follicular lymphoblastoma at the top as most radiosensitive, and follows it with lymphatic leukemia, lymphosarcoma, polymorphous-cell sarcoma, and Hodgkin's disease.

A therapeutic test is recommended for deep-seated tumors in which biopsy is not feasible, such as mediastinal masses. In such tumors, the author believes, lymphatic leukemia is easily excluded by examination of blood and bone-marrow preparations. If this diagnosis has been ruled out, he then measures the size of the mass on an x-ray film, and then gives 600 roentgens to the lesion in two days, and re-x-rays and measures the mass three days later. If there has been a decrease in the size of the mass of 25 per cent or more, a diagnosis of giant follicular lymphoblastoma or of lymphosarcoma is in order, and a tumor-killing dose of x-ray is given. Recurrence after this suggests lymphosarcoma.

If the second x-ray examination shows no diminution in the size of the tumor, the author gives further irradiation to the tumor. If regression occurs when 1200 to 2000 roentgens have been given, the mass is considered a polymorphous-cell sarcoma. If regression occurs only after 2000 to 3000 roentgens, the mass is probably Hodgkin's disease. If no response has occurred after 3,000 roentgens have been given, the mass is radioresistant and probably belongs to a heterogeneous category including neurogenic sarcoma, carcinoma, various cysts, etc.

There is no discussion in the article of other forms of therapy of lymphomata, such as the nitrogen mustards.

S E

L'ANEMIE DE LA MALADIE DE HODGKIN (The anemia of Hodgkin's disease) *Georges Marchal* (Paris) *Rev. Hemat.* 2 479-497, 1947

Anemia is generally considered as a sign of slight importance in the course of Hodgkin's disease. Marchal, on the contrary, considers it as an important factor and one of the essential signs of malignity. He has made a very comprehensive and well documented study of it.

Clinically, the author distinguishes three forms: anemias of an acute type, anemias connected with bony involvement, and anemia with splenomegaly. Clinical, anatomic and experimental studies show

that the mechanism of these anemias is essentially hemolytic (shown by the reticulocytosis and the indirect bilirubinemia) and also erythrophagic (shown by the macrophage hyperplasia found particularly in the spleen)

J.P.S.

IMMUNOHEMATOLOGY

PREPARATION FROM HUMAN RED CELLS OF A SUBSTANCE INHIBITING VIRUS HEMAGGLUTINATION P. M. de Burgh, Pen-Chung Yu, C. Houe, and M. Bournick From the Department of Bacteriology and Immunology, Harvard Medical School, Boston, Mass J. Exper. Med. 87: 1-9, 1948

Methods are described for extraction and purification of a substance inhibiting the agglutination of red cells by influenza (PR8) and mumps viruses. Human red cells of all types served as the chief source of inhibitor, activity being associated with the elinin fraction rather than with the stromatin fraction described by Calvin and coworkers. Material having similar properties was also found in human lung, but not in human liver, kidney or serum.

Active extracts were purified to the extent that 0.1 gamma of material inhibited one hemagglutinating dose of virus. The most highly purified fractions contained 2.6 per cent nitrogen, at least 50 per cent of polysaccharide, and no phosphorus. In the ultracentrifuge the purified preparation behaved as a polydisperse macromolecular substance. The active material was obtained from red cell stroma in an ether and chloroform-soluble form which, on further treatment, was converted into a chloroform insoluble form. It is considered possible that the former represents more closely the virus receptor as it exists in the intact cell.

The purified inhibitor was inactivated on incubation with virus at 37 C.

This report, and many others in the recent literature, serve to emphasize the importance of virus red cell relationships. It seems likely that further attempts to purify the various substances present in erythrocyte stroma may produce results that will aid in clarifying the nature of viral parasitism. The possible therapeutic implications of these studies are also apparent.

IRON AND PORPHYRIN METABOLISM

STUDIES ON THE TRANSPORTATION AND METABOLISM OF IRON IN THE BODY C.-B. Laurell From the Central Laboratory, University Hospital, Lund, Sweden Acta physiol. scand. Vol. 14, Suppl. 46, 1947

The work begins with a discussion of previous results regarding the transportation of iron. A short survey of the importance of the serum iron fraction is also given, together with a discussion of the iron binding capacity of serum. In this connection, the author mentions some of his own experiments aiming at an isolation of the specific iron-binding protein in the serum.

Holmberg's and Laurell's earlier work on the saturation limit for iron in the serum shows that there is a mean value of 312 gamma per cent for this limit, which agrees quite well with the mean maximal serum iron concentration of 291 gamma per cent found by Waldenström after the intravenous injection of iron into normal subjects. The iron-binding capacity of the serum is usually not fully utilized. The difference between the actual amount of serum iron and the saturation limit is called latent capacity. Above this saturation limit, the iron is loosely bound and reacts with phenanthroline directly. After a discussion of the different methods invented and used by the author, he finds that an indirect method is the easiest and best for the determination of the saturation limit. In the next chapter, the mode of binding of iron that has been added to the serum in vitro is discussed. With the aid of a number of ingenious adsorption experiments, the author shows that up to a certain concentration, iron is firmly bound and cannot be adsorbed. This holds true for both ferric and ferrous iron. The natural occurrence of ferric or ferrous iron linked with the serum protein cannot be determined. A large number of dialyzing experiments against serum seem to show that iron above the saturation limit is easily dialyzable and thus loosely bound. This would explain why the toxic effects of intravenously injected iron are seen only when the ceiling observed by Waldenström was reached. This ceiling thus corresponds to the saturation limit.

In some later experiments it was shown that the iron may be liberated from the natural serum iron complex without changing the capacity for iron-binding of this protein. The process is thus reversible.

The mean value for the saturation limit in a number of normal persons was found to be $315 \pm 33\%$ per cent. Ingestion of iron does not increase the iron-binding capacity of the serum and the author concludes that the iron must leave the mucosa in ionized form and not as an iron-protein complex.

During the latter part of pregnancy, the values for the serum iron show a steady rise. There is a drop immediately before parturition. A study of maternal and fetal blood gives some interesting pieces of information. It is obvious that the iron-binding component of the maternal serum cannot pass freely through the placenta.

In posthemorrhagic anemia, the saturation limit is high but the serum iron values low. In untreated pernicious anemia, the mean saturation values were lowered (236% per cent). The saturation limit was not affected by the rapid drop in serum iron under treatment. The limit was low in acute infections and paralleled the drop in the serum iron value. Cirrhosis of the liver and uremia showed a very low limit.

The work ends with a discussion of the theoretic implications of these results.

In a later paper published with Ingelman in *Acta chem scand*, the author has given a more detailed account of his preparative work. Swine serum was used for the experiments as it shows very little color from bilirubin. It is therefore easier to use the color intensity of the iron binding protein as an indicator for further fractionations. After addition of ferrous salts the color of the serum becomes reddish. Ammonium sulphate was added up to 60 per cent saturation. The precipitate was separated and about 90 per cent of the iron-binding component was still present in the solution. When the salt concentration was increased to 75 per cent, albumin and the iron containing protein came down as a precipitate, it was redissolved and dialyzed free from salt at pH 5.2 at 0°C . Ethyl alcohol was added to give a concentration of 20 volumes per cent. The solution was brilliantly red after the removal of the precipitate. After further precipitation of a new fraction, the solution of the iron containing protein was left at -15° , when this protein was precipitated as a red sediment. Judging from its solubility in concentrated electrolyte solutions this protein cannot be regarded as a globulin. On electrophoresis, the isoelectric point was found to be about 4.4. At ultracentrifugation, the sedimentation constant was found to be 5.8. The diffusion constant was 5.8×10^{-7} . The parcel specific volume was not determined and the value given by Cohn and colleagues for their iron binding β -globulin was used for the calculation of the molecular weight. It was found to be 88,000. This agrees very well with the value given by Cohn for the metal-combining protein, but the isoelectric point was found by Cohn to be 5.6.

J W

SERUM IRON LEVELS IN ADOLESCENT GIRLS. A STUDY OF THREE CASES. *F. A. Johnston* From the Department of Home Economics, University of Chicago, Chicago, Ill. *Am J Dis Child* 74: 716-721, 1947.

The concentration of iron in the serum was determined eleven times over a period of five months in 3 adolescent girls whose well controlled diet contained 4 to 5 mg, then 9 mg and 11 mg iron per day for the three successive periods of the study. This investigation was carried out with the expectation that changes in serum iron on a controlled diet might provide an estimate of the iron requirement for growth and menstruation.

Hemoglobin levels of the subjects were near average values for girls, while the mean serum iron concentrations of 72, 62 and 46 micrograms per 100 cc respectively were low, thus suggesting that serum iron might be more sensitive than hemoglobin as an index of iron stores. Since serum iron levels did not fall significantly, however, over a nine week period on low iron intake or rise over a period of twelve weeks on a fair iron intake, it was concluded that serum iron concentration does not respond to dietary intake quickly enough for use as a criterion of adequacy in short-term studies.

L E Y

A MICROMETHOD FOR THE QUANTITATIVE DETERMINATION OF THE URINARY COPROPORPHYRIN ISOMERS (I AND III). *S. Schwartz, V. Haukinson, S. Cohen, and C. J. Watson*, From the Department of Medicine, University of Minnesota Hospital, Minneapolis, Minn., and the Metallurgical Laboratory, University of Chicago, Chicago, Ill. *J Biol Chem* 168: 133-144, 1947.

A method is described for the extraction of coproporphyrin quantitatively from 100 cc aliquots of urine and for its measurement fluorophotometrically. There are two alternate procedures for further purification and for isomer analysis, both dependent on the difference in fluorescence stability of the two porphyrin methyl esters in 30 to 35 per cent aqueous acetone in the cold.

C A F

PORPHYRIA AND PORPHYRINURIA REPORT OF A CASE, REVIEW OF PORPHYRIN METABOLISM WITH A STUDY OF CONGENITAL PORPHYRIA I *Dunsky, S Freeman and S Gibson* From the Children's Memorial Hospital and the Department of Physiology, Northwestern University Medical School, Chicago, Ill Am J Dis Child 74 305-320, 1947

A case of congenital porphyria in a 17 month old girl is presented and its significance as related to an understanding of normal and pathologic pigment metabolism is emphasized. The clinical features of the case included red urine, erythrodontia, hydrot-aestivale and hirsutism. Analysis of the urine revealed the presence of uroporphyrin I and coproporphyrin I in addition to an unidentified porphyrin, the methyl ester of which melted at 209° to 212°C. The feces contained coproporphyrin I and another porphyrin with a somewhat higher melting point, but no uroporphyrin I was detected in the feces. A concise review of the literature on porphyrin metabolism is included in the report.

L.E.Y

HEMOGLOBINURIA

THE INFLUENCE OF AVAILABLE FLUID ON THE PRODUCTION OF EXPERIMENTAL HEMOGLOBINURIC NEPHROSIS IN RABBITS J J *Lalich* From the Department of Pathology, University of Wisconsin Medical School, Madison, Wisconsin J Exper Med 87 157-162, 1948

Available fluid was measured by the thiocyanate method before and after a three day period of water deprivation in 20 rabbits, 15 of which were then given nine or ten intravenous injections of hemoglobin, totalling 1.8 Gm per Kg over a three day period. Wide variation in available fluid was found in different animals, especially in the females, some of which had appreciably lower volumes than any of the males. Wide variation was also noted in response to water deprivation. Inverse relationship is claimed between quantity of available fluid and severity of hemoglobinuric nephrosis, but the number of animals in each category is too small to permit conclusions in this respect. It should be noted, moreover, that during the period of hemoglobin injection all of the rabbits that urinated had an acid urine. The deleterious effect of dehydration might have been more clearly established if alkalinity of the urine could have been maintained.

Intravenously administered hemoglobin solutions were found to exert a diuretic effect in 3 of 7 rabbits tested, but when available fluid was depleted, elimination of hemoglobin appeared to be delayed or inhibited. It is postulated that under such circumstances, hemoglobin enters the renal tubules, pigment casts are formed, degeneration of tubular epithelium appears and uremia follows.

Additional findings of interest were necrosis of the liver and pulmonary edema in some of the rabbits that died of uremia. The combined weight of the kidneys of rabbits dying of hemoglobinuric nephrosis was significantly in excess of that of the control rabbits and of the test animals with transient nephrosis.

L.E.Y

RENAL ATROCYTOSIS AND INTRACELLULAR DIGESTION OF INTRAPERITONEALLY INJECTED HEMOGLOBIN IN RATS L J *Rather* From the Department of Pathology, Stanford University School of Medicine, San Francisco, Calif J Exper Med 87 163-174, 1948

Rats were injected intraperitoneally with solutions of human hemoglobin in total doses averaging 5 Gm per Kg. Serum hemoglobin concentration, rate of excretion of hemoglobin in the urine and urine output were measured, and the rats were then killed at varying intervals for the purpose of studying the tissues.

In rats killed two hours after the first injection of hemoglobin, discrete bodies with the staining characteristics (Dunn's stain) of hemoglobin were found in small numbers within the epithelium of the proximal convoluted tubules. In rats killed at seventeen hours, the renal epithelium was packed with these particles, and it was found that formation of casts did not occur to any extent until the amount of atrocytosed material reached a maximum. Although it was inferred that break-up of the hemoglobin began prior to release of inorganic iron, the appearance of hemosiderin was the first visible evidence of intracellular splitting of hemoglobin. Deposits of hemosiderin were most marked at about sixty five hours after which time they slowly disappeared. It is of interest that very little hemosiderin and no hemoglobin were demonstrable in the parenchymal or Kupffer cells of the liver, nor in phagocytic cells of spleen or femoral marrow.

There was no evidence that intracellular accumulation of hemoglobin damaged renal epithelium, and it was not until large amounts of hemoglobin were present within lumina of the nephrons that injury could be detected. Oliguria was attributed to interference with flow through lumina due to increased viscosity of protein-rich fluid.

These observations are in general agreement with those reported by other investigators and they support the hypothesis that hemoglobin filtered by glomeruli undergoes athrocytosis by tubular cells and is then returned to the blood in a simpler form.

CONVENTION NOTES

INTERNATIONAL SOCIETY OF HEMATOLOGY

BUFFALO, N Y, AUGUST 23-26, 1948

THE International Society of Hematology is to hold its first formal meeting in Buffalo, August 23-26, 1948. Conceived in Dallas, Texas, in 1946 during the first part of an International Rh and Hematology Conference, the Society began to assume form when the decision to go ahead with its organization was made during the second part of the Conference in Mexico City in November 1946. The guiding spirits of the new organization were Drs. Joseph M. Hill and Sol Haberman of Dallas, Texas. It was fitting, therefore, that these two were later elected president and secretary respectively. Dr. Eduardo Uribe Guerola, of Mexico, was elected Vice-President and Dr. W. Stuart Stanbury, of Canada, was elected as treasurer.

It was decided that hematology had become of sufficiently impelling interest to so many individuals throughout the world that an organization devoted to this interest was fully justified. It was believed that the convening of different groups of individuals—clinicians, pathologists, chemists, immunologists and the like—would offer distinct benefits to all concerned. It was felt that the gathering of individuals from different parts of the world would help to foster important relationships and to break down the barriers of the printed word. For these reasons a truly International Society was envisaged.

A *membership committee* was appointed consisting of the following individuals:

William Dameshek, Chairman Boston, Mass.	Moises Chediák Havana	Alfredo Pavlovsky Buenos Aires, Argentina
R. Philip Custer Philadelphia, Pa.	Walter Cruz Rio de Janeiro	Robert R. Race London
O. P. Jones Buffalo, N. Y.	Henrik Dam Copenhagen	Karl Rohr Zurich
Roy Kracke Birmingham, Ala.	C. R. Das Gupta Calcutta	Luis Sandoval S. Santiago, Chile
Philip Levine Raritan, N. J.	D. diGuglielmo Naples	Rod Sirivekul Bangkok, Siam
M. Bessis Paris	I. González-Guzmán Mexico, D. F.	Theodore Waugh Montreal
Berger Broman Stockholm	Ludwik Hirsztfeld Wrocław, Poland	

It is planned to have at least two categories of members, senior and associate, but the final regulations for membership have not as yet been completed. It is believed that each country or group of countries should be free to carry out its own membership admissions in a more or less autonomous manner, subject to general

rules to be decided upon at the first meeting of the *constitution committee* The latter committee is composed of the following

Israel Davidsohn, Chairman
Chicago

I Gutierrez Villegas
Mexico, D F

A H T Robb Smith
Oxford, England

Joseph Ross
Boston

L M Tocantins
Philadelphia

PROGRAM NOTES AND NEWS

The meeting promises to be a landmark in the field of hematology not only because it will mark the first truly International Congress in that field, but because of the enthusiastic interest being shown by people from all over the world All those interested in hematology are invited to this meeting Headquarters will be at the Hotel Statler, Buffalo, New York All inquiries regarding program, exhibits, etc are to be forwarded to Dr Sol Haberman, Secretary For further information, see box on page 725

The program committee for the Buffalo meeting is as follows

Ernest Witebsky, Chairman
Buffalo

Louis K Diamond
Boston

Carl Moore
St Louis

Walter Seegers
Detroit

L H Snyder
Norman, Oklahoma

Eduardo Uribe Guerola
Mexico, D F

Lionel Whitby
Cambridge, England

TENTATIVE PROGRAM

Day 1	One-half day	Methods including phase microscopy, electron microscopy, and histo-chemical methods
	One-half day	Hemorrhagic diseases
Day 2		Red cell problems Anemia
Day 3		Hemolytic Anemia and Immunohematology
Day 4		White cell problems Leukemia, Lymphoma

In addition to the speakers listed on the next page, it is planned to hold a certain number of round table discussions

Dr Oliver P Jones of Buffalo, the chairman of the committee on exhibits has announced that a number of exhibits both professional and commercial are in process of preparation A preliminary list of exhibits and exhibitors is given on pages 724-726 Other Committees and Chairmen appointed for the Meeting are *Accommodations*, L Edgar Hummel, M D , Buffalo, N Y , *Publicity*, David K Miller, M D , Buffalo, N Y , *Banquet*, Douglas P Arnold, M D , Buffalo, N Y , *Local Information*, E George Phillies, M D , *Registration*, Stuart L Vaughan, M D , *Women's Activities*, Mrs Mildred Lockwood, *Excursion and Entertainment*, Charles Becker, M D , *Equipment* (Co-chairmen), Siegfried Tannhauser, M D , and James F Mohn, M D

SOME OF THE SPEAKERS AND THEIR SUBJECTS

- Oliver P Jones, University of Buffalo, Buffalo, New York
Newer Interpretations of Nuclear Pattern of Immature Blood Cells
- L B Jaques, University of Saskatchewan, Saskatoon, Saskatchewan, Canada
Studies on the Silicone Technic for Delaying Blood Coagulation
- L K Diamond, Harvard Medical School, Children's Hospital, Boston, Mass
Congenital Absence of Fibrinogen
- Clement A Finch, Peter Bent Brigham Hospital, Boston, Mass
Iron Metabolism in Hemochromatosis
- John G Gibson, 2nd, Harvard Medical School, Boston, Mass
Determination of the Zinc Content of Normal Human Erythrocytes, Leucocytes, Plasma and Whole Blood
- R G MacFarlane, Radcliffe Infirmary, Oxford, England
Problems of Coagulation and Hemorrhagic Diseases
- Elbert deCoursey, Brooke General Hospital, San Antonio, Texas
Effects of Lethal Instantaneous Ionizing Radiation upon the Reticulo-endothelial System
- M Hynes, Cambridge University, Cambridge, England
The Iron Reserves of a Normal Man
- Floyd Daft, National Institute of Health, Bethesda, Maryland
Interchangeability of Folic Acid, Other Vitamins and Amino Acids in the Correction of Experimental Blood Dyscrasias
- A H T Robb-Smith, Radcliffe Infirmary, Oxford, England
The Effects of Transfusion Hemosiderosis
- D Shemin, Columbia University, New York City
The Biologic Synthesis and Metabolism of Porphyrins
- Walter H Seegers and Arnold G Ware, Wayne University, Detroit, Michigan
Activation of Purified Prothrombin
- Robin Coombs, University of Cambridge, Cambridge, England
Observations on Some of the Immunological Processes Concerned in the Diagnosis and Manifestations of Hemolytic Disease of the Newborn
- R R Race, Lister Institute, London, England
Blood Groups and Their Inheritance with Particular Reference to the Rh and MN Systems
- J J van Loghem, Binnengasthuis, Amsterdam, Holland
ABO Incompatibility and Rh Antagonism
- G Failla, Columbia University Medical Center, New York City
Correlation of Radiation Dose and Effect on Hemapoietic System
- Maurice Bessis, Paris, France
Exchange Transfusion in Diseases Other than Hemolytic Disease of the Newborn
- W Jacobson, School of Medicine, University of Texas, Corpus Christi, Texas

INFORMATION

- First formal meeting, INTERNATIONAL SOCIETY OF HEMATOLOGY
- AUGUST 23-26, 1948
- BUFFALO, N Y , Headquarters, STATLER HOTEL
- All those interested in hematology may attend

REGISTRATION FEE Ten dollars*

For information regarding program, exhibits, etc , contact Dr Sol Haberman,
Secretary, 3301 Junius St , Dallas, Texas

For information regarding hotel reservations, contact Dr Edgar Hummell,
University of Buffalo, Buffalo, N Y , Chairman of the Accommodations
Committee See reservation information and form, page 727

* Interns and residents and guests from those countries which at present are having a dollar shortage (i e certain European and Asiatic countries) will be exempt from the registration fee. This fee likewise does not apply to sponsors and those presenting scientific exhibits at the Congress.

LIST OF EXHIBITORS AT THE INTERNATIONAL HEMATOLOGY CONGRESS AND PROPOSED TITLES (*Continued*)

Rubinstein, Michael A , New York, New York	Aspiration of Bone Marrow from the Iliac Crest
Schwartz, Steven O , Chicago, Illinois Co-exhibitors Dr W J Kawula and Dr S R Kaplan	Thrombocytopenic Purpura
Singer, Karl, Michael Reese Hospital, Chicago, Illinois	Studies on the survival time of red cells in health and disease
Smith, Carl, 103 E 84th St , New York, N Y	Outpatient Transfusion Clinic for Ambulatory Patients with Mediterranean and Other Chronic Anemias
Stanbury, W S , Calgary, Alberta	' Miracle Fluid ' (film)
Sundberg, Dorothy, Institute of Anatomy, University of Minnesota, Minneapolis, Minn	Granulomatous Lesions in Bone Marrow Obtained by the Aspiration Method
Tompkins, Edna H , Laboratory of Applied Physiology, Yale University, New Haven, Conn	Avoidance of Errors in Use of Hayem's Fluid
Ware, Arnold G , Department of Physiology, Wayne University College of Medicine, Detroit, Michigan Co-exhibitor Dr John Fahey	The 2 stage Analysis for Prothrombin and Ac globulin
Wiener, Alexander S , Brooklyn, New York	Rh-Hr Blood Types and the Heredity—also the Rh Antibodies and their mode of action
Young, Lawrence E , University of Rochester, School of Medicine and Dentistry, Rochester, New York Co-exhibitor Dr D Ervin	Hemolytic Transfusion Reactions (Destruction of A1 and A2 cells by transfusion of blood from a dangerous universal donor)

COMMERCIAL EXHIBITS

In addition to the preceding list of scientific exhibits, a variety of commercial exhibits is planned. The following list of exhibitors is incomplete, as requests for exhibit space were still being received as this goes to press.

Vend All Limited	Hospital Liquids Incorporated
Lederle Laboratories	Technicon Company
Cutter Laboratories	Bausch & Lomb Company
Armour Laboratories	Grune & Stratton

The Society is obtaining financial assistance from several sources to allay the expenses of the Congress. These financial contributors are tentatively listed in two classes. Patrons, who have contributed \$1,000 or more, Sponsors, who have contributed between \$500 and \$1,000. The following list, to which additions may be expected, is complete as of press time.

PATRONS

Lederle Laboratories Division, American Cyanamid Company, New York, N Y
Hoblitzelle Foundation, Dallas, Texas

University of Buffalo, Buffalo, N Y
Parke, Davis & Company, Detroit, Mich

SPONSORS

Armour Laboratories, Armour & Company, Chicago, Ill
Hospital Liquids, Incorporated, Chicago, Ill

American Optical Company, Scientific Instruments Division, New York, N Y

INFORMATION FOR HOTEL ACCOMMODATIONS

For your convenience in making hotel reservations for the coming meeting of the International Society of Hematology, August 23-26, 1948, in Buffalo, New York, hotels and their rates are listed below. The meetings are to be held at the Hotel Statler and a total of 350 rooms are being held in reserve. However, those attending the meetings may apply for rooms at any of the hotels they desire, all of which, in the list below, are relatively near and convenient to the convention hotel. Those planning to attend from countries other than the United States and Canada may, if they choose, fill in the form below, detach and return as directed. The local committee will then make reservations as near to their indicated wishes as possible. *Such request should be sent in time to be received in Buffalo not later than August 1, 1948, and must give the date and hour of arrival as well as definite date and approximate hour of departure, names and addresses of all persons who will occupy reservations must be included.* The Hotel Statler, upon request, is anxious to send a questionnaire card to those interested in obtaining reservations at the convention hotel.

RATES (Minimum)

	Single	Double	Twin
Hotel Buffalo, Washington and Swan Sts	\$2 50 up	\$4 50 up	\$5 00 up
Hotel Lafayette, Washington and Clinton Sts	3 50 up	6 50 up	7 00 up
Hotel Lenox, North near Delaware Ave	4 00 up	6 00 up	6 00 up
Hotel Markeen, Main at Utica St	2 25 up	3 50 up	
Hotel Richford, 210 Delaware Ave	2 00 up	3 50 up	5 00 up
The Sheraton, 715 Delaware Ave	3 50 up	6 00 up	6 50 up
Hotel Statler, Delaware Ave at Niagara Sq	3 50 up	5 75 up	7 00 up
Hotel Stuyvesant, 245 Elmwood Ave	3 50 up	5 50 up	
Hotel Touraine, 274 Delaware Ave	3 50 up	5 50 up	7 00 up

For tourist information and resort accommodations, write to Buffalo Convention & Tourist Bureau, Inc., Buffalo 2, New York, U S A

(TO BE USED ONLY BY THOSE ATTENDING FROM COUNTRIES OTHER THAN THE UNITED STATES AND CANADA)

ALL RESERVATIONS MUST BE RECEIVED NOT LATER THAN AUGUST 1, 1948

L E HUMMEL, M D

Chairman, Committee on Accommodations

537 Delaware Avenue

Buffalo 2, New York, U S A

Please reserve the following accommodations for the meeting of the International Society of Hematology, to be held in Buffalo, N Y, August 23-26, 1948

Single Room	Double Bedded Room	Twin Bedded Room
Rate From \$	to \$	First Choice Hotel
		Second Choice Hotel
		Third Choice Hotel

Arriving at Hotel (date) Hour A M P M Leaving

THE NAME OF EACH HOTEL GUEST MUST BE LISTED. Therefore, please include the names of both persons for each double or twin bedded room requested.

Names and addresses of all persons for whom you are requesting reservations and who will occupy the rooms asked for

If the hotels of your choice are unable to accept your reservation the Com-

BOOK REVIEWS

Pathologisch-anatomische Untersuchungen über Leberzirrhose bei Säuglingen und Kleinkindern (infantile Leberzirrhose) mit endemischer Häufung By HERMANN GÖGL Vienna, Wilhelm Maudrich, 1947

This monograph, by Dr Hermann Gögl of Innsbruck, is an interesting study of 24 cases of infantile cirrhosis in which the general picture is that of a chronic hepatitis with diffuse cirrhosis in varying degree. Other changes serving to characterize these cirrhoses from a histologic standpoint are the presence of eosinophilic and sometimes basophilic granules within the liver cells, and at times of inclusion-like bodies, suggesting a virus infection. Gögl points out that this disease is common in the Tyrol and Vorarlberg regions of Austria, but more particularly around the town of Kitzbühl where it seems to have endemic character. He obviously leans toward a virus etiology of his own cases but for lack of evidence is obliged to leave the question open as to exact etiologic agents and the relation to epidemic hepatitis.

In addition to the careful clinical, anatomic, and histologic descriptions, the latter supplemented with reasonably satisfactory photomicrographs, there is an extensive bibliography on the subject of cirrhosis in infancy and early childhood.

C J WATSON

Der Blutspender By H. WILLENEGGER AND R. BOITEL Benno Schwabe & Co., Basel (Switzerland), 1947
Pp 197, 10 francs

This is a unique work, as books about blood transfusions and blood banks go. The literature to date has emphasized blood groups and transfusion reactions, the management of blood banks and the latest discoveries arising from physico-chemical manipulations of whole blood and its constituents. This book, however, treats of the blood donor, the fountainhead and mainstay of all this activity and the forgotten man of most publications. The uniqueness of the point of view alone would justify the writing of such a book. This small volume, however, has even more to recommend it. Although the main interest centers about the blood donor and the social significance of his service in contemporary society, the scope of the work is wider and comprises many of the problems accompanying the therapeutic use of blood and plasma.

An illustrated historical account of the development of blood transfusions opens the book and is carried up to modern times and the use of fresh and reconstituted plasma. There follows an excellent discussion of the individual blood donor, his physical and psychologic examination, the question of payment, and the problem of transmission of disease from donor to recipient, with special emphasis on syphilis. The blood groups are briefly but adequately presented in a clearly diagrammed manner, although the Rh complex is summarily treated in one short paragraph and presents the state of knowledge of early 1942. The major and most interesting portion of the book deals with the rise of blood donor organizations in modern society. It stresses the social aspects of the problem of an adequate supply of blood donors in the face of mounting use of blood transfusions. The development of blood donor societies in each of the major countries is individually outlined and the types of organizations are discussed and criticized.

This book is written in a simple style, almost as if it were intended more for the general lay public than for the medical profession. However, it does give an excellent general review of the whole problem of an adequate source of supply of human blood, and the methods, both organizational and psychologic, by which such a source might be set up. It is certainly advantageous reading for all those physicians actively associated with blood banks and blood transfusion services.

RELATION OF ADRENAL CORTICAL HORMONE TO LYMPHOID TISSUE AND LYMPHOCYTES

B₃ WILLIAM N VALENTINE, M D , CHARLES G CRADDOCK, JR , M D , AND
JOHN S LAWRENCE, M D

GENERAL INTRODUCTION

THE CONCEPT of hormonal control of the numbers of the circulating blood lymphocytes is not new. The remarkably narrow range of fluctuation of blood cells under normal circumstances has long stimulated scientific investigators to speculate over the manner of their regulation. The possibility of a humoral mechanism has intrigued many. The literature pertinent to humoral theories of regulation of the blood lymphocytes has been reviewed by Drinker and Yoffey²² in their monograph published in 1941. At the time of the review, no humoral theory had gained wide acceptance.

Within the last few years, interest in the hormonal control of the blood lymphocytes has been stimulated by a large number of reports suggesting the pituitary-adrenal cortical control of lymphoid tissue structure and function, including the regulation of the numbers of circulating lymphocytes. It has been postulated that the secretion of the adrenal cortex (more specifically the sugar hormone) is the normal determinant of the numbers of blood lymphocytes. Fitted into the broader pattern of the alarm reaction and adaptation syndrome of Selye, offering as it does new vistas of the physiology of lymphoid tissue, and illuminating the poorly understood functions of the lymphocyte, this concept demands the careful and critical scrutiny of all the facts on which it is based.

It is the object of this report (1) to present experimental data on the effect of adrenal cortical hormone on the numbers of thoracic duct lymphocytes and on the rate of flow of thoracic duct lymph in the normal and adrenalectomized cat, (2) to briefly present data on the peripheral blood counts of cats before and after adrenalectomy, (3) to recapitulate in considerable detail as much as possible of the actual published data relating to hypophyseo-adrenal cortical control of lymphoid tissue structure and function and of the numbers of blood lymphocytes. To this latter end the second part of this communication is devoted to critical review of the subject,

it being hoped that the assemblage of the available experimental data will better permit a dispassionate analysis of the present status of the hormonal control of lymphocytes and lymphoid tissue

PART I

A EXPERIMENTAL STUDIES ON THE EFFECT OF ADRENAL CORTICAL EXTRACT ON THE NUMBERS OF LYMPHOCYTES AND RATE OF FLOW OF THORACIC DUCT LYMPH

Introduction

Only two previous reports are available on the effects of adrenal cortical extract or adrenocorticotrophic hormone on the output of thoracic duct lymphocytes in the experimental animal. The first of these, a short preliminary communication by Reinhardt and Li,⁵⁶ reported marked reduction in the number of thoracic duct lymphocytes in rats following the subcutaneous or intraperitoneal injection of 1 to 6 mg. of pure adrenocorticotrophic hormone. This was apparent within fifteen to thirty minutes after injection and lasted four to ten hours. No data are presented on the number of animals used or the findings in individual animals. The common lymph sacs of rats anesthetized with sodium pentobarbitol were intermittently cannulated in this group of experiments and leukocyte counts obtained at thirty to sixty minute intervals for several hours before and after the administration of hormone. The authors conclude that "it may be generalized that the lymphocyte level of the circulating blood is under direct adrenal cortical control."

In 1946, observations by Yoffey, Reiss, and Baxter⁷³ on the influence of adrenocorticotrophic hormone on the rate of lymph flow and numbers of lymphocytes in thoracic duct lymph appeared in the British literature. These investigators found a decrease in the lymphocyte count and volume of flow of thoracic duct lymph in cats after administration of 300 units of adrenocorticotrophic hormone. In the data presented from a single, typical experiment flow reduction from 2 to 3 cu. cm. an hour to 1 cu. cm. an hour was observed. Lymphocyte counts were reported as having fallen to somewhere below 10,000 per cu. cm. two to three hours after hormone administration, the pre-injection count being in the neighborhood of 50,000 to 60,000 lymphocytes per cu. cm.

The measurement of the influence of adrenal cortical extract on numbers of thoracic duct lymphocytes entering the blood stream is a particularly pertinent part of the investigation of the hypothesis of adrenal cortical control of lymphoid tissue structure and function and of the numbers of circulating lymphocytes. Although there has been some speculation, there is virtually no evidence of an abnormal rate of disappearance of lymphocytes from the peripheral blood under the influence of increased adrenal cortical activity. The literature in regard to adrenal cortical regulation of blood lymphocyte levels will be carefully examined in the second part of this report. Suffice it to say that the latter postulate rests heavily upon the histologic and functional alterations produced by the sugar hormone of the adrenal cortex in lymphoid structures themselves. The available evidence lays emphasis on involutionary changes wrought by adrenal cortical activity on the factories manufacturing lymphocytes, on the temporary cessation of lymphocyte production, and

on the dissolution of lymphocytes within the lymphoid tissues. It should then be possible to obtain confirmation or refutation of alterations in the rate of delivery of lymphocytes to the blood by examination and study of the volume of lymph and numbers of lymphocytes in thoracic duct lymph at the point of its entrance into the venous circulation. Although not all of the lymphocytes enter the blood by this route, it is such a preponderant and major source of blood lymphocytes that it appears reasonable to feel that any widespread interference with lymphocyte production would be reflected by changes in thoracic duct lymph. The present data in the literature are fragmentary and scanty. This investigation was therefore undertaken with the hope of adding direct observations on the delivery of lymphocytes to the systemic circulation by thoracic duct lymph before and after the injection of adrenal cortical hormone.

Experimental Approach and Methods

Although direct observation of lymphocytes in thoracic duct lymph is an appealing approach and offers many advantages, the problem of control is a difficult one. First, it is widely recognized that the numbers of lymphocytes in any given drop of lymph may vary tremendously in the same animal. Second, it is also a matter of record that thoracic duct lymphocyte production may show very wide variations from one animal to another. Age, general health, individual peculiarities and numerous other considerations of undetermined nature are all probably important in this regard. Third, lymph flow is influenced by many factors such as the time relationships with feeding, the nature of ingested food, the variations in muscular tone induced by varying depths of anesthesia, etc. Fourth, the mechanical factors incident to cannulation of the thoracic duct and the mere fact that lymph is lost from the body may well result over a period of hours in qualitative or quantitative alterations of the lymph. These alterations may conceivably make their appearance only after a considerable interval of time. Fifth, physiologic increase in the activity of the intact adrenals of the experimental animal may well occur as a result of the alarming stimulus of the operative procedure of thoracic duct cannulation itself. An alarm reaction may mask the effect of injected hormone and may vary in intensity from animal to animal.

With these considerations in mind it is apparent that each cannulated animal receiving adrenal cortical extract must have all comparisons made in terms of *its own* baseline determinations obtained prior to injection of hormone. It is not possible to quantitatively compare absolute values for thoracic duct lymphocytes of one animal to another. However, if in each animal one expresses these values for each given time interval after injection as a ratio or percentage of pre-injection values, it is possible to compare these *ratios or percentages* from animal to animal. Since in each animal the evaluation of the effect of hormone depends upon relatively few observations, it is highly important in this type of experiment to compare values obtained from large quantities of lymph so that the wide variations in numbers of cells present in any one drop of lymph may be minimized. Since the effect of hormone is determined for each animal individually the necessity for complete uniformity of all factors in all animals is to a large extent mitigated. It is important, however, that enough experiments be done to determine the presence or absence of any significant trend and that the experiments be of sufficient duration to cover the period when effects would be expected.

It is also apparent that if the effects of the procedure itself are to be ruled out, a control group of animals not injected with hormone but handled in an identical manner as the experimental group must be obtained. Valid comparisons can only be made between values obtained in experimental and control animals at the same interval of time after thoracic duct cannulation. Changes noted without benefit of a control group could otherwise easily be due to the procedure itself. If the possibility of adrenal activity incident to an alarm reaction is to be ruled out as an uncontrolled variable the experimental animal must include an adrenalectomized group. An attempt was made in so far as possible to control the effects by the following experimental procedure.

The experimental animal employed was the cat. Animals were divided into three groups. Group I consisted of control normal animals which were to receive no injections of adrenal cortical hormone. Group

II consisted of normal animals which were to receive injections of adrenal cortical hormone. Group III consisted of bilaterally adrenalectomized cats which were likewise to receive injections of adrenal cortical extract. In all groups studied the same procedure was followed. Under anesthesia induced by the intraperitoneal injection of sodium pentobarbital, the thoracic duct was exposed at its entrance into the venous circulation in the neck. Whenever the presence of a single main duct permitted it, cannulation of the thoracic duct itself was performed, a small glass cannula being inserted into the duct and held in place by a ligature. Any small subsidiary ducts were tied off. In a few instances where multiple small ducts entered a segment of vein the latter was isolated from all connection with the circulation and cannulated. Not all animals of course can be successfully cannulated. Also, in some instances small collateral ducts must be ligated and there is some doubt that lymph flowing from the cannula is completely equivalent to the entire volume of lymph normally entering by the complete ductal system. However, it certainly constitutes the major portion of the original total flow, and since results in each animal are referred only to baseline determinations in the same animal this is not an important point. It is important that a satisfactory cannulation and reasonably adequate lymph flow be obtained in each experiment. It was customary to place a small amount of 1 per cent sodium heparin in the cannula to prevent any clotting of lymph while cannulation was in progress. On completing the procedure the animal was turned in the prone position and placed on a wooden support. A small oval aperture in this support under the cannulated duct permitted the latter to hang down at a roughly 45 degree angle and to deliver its lymph by dripping freely into a collecting tube. The cannula was allowed to drip for a few minutes before collection was started in order to clear itself of heparin and to relieve any abnormal backlog of lymph which might have accumulated in the ductal system while cannulation was being performed.

The collecting container consisted of a glass centrifuge tube calibrated so that lymph volumes could be directly measured. This was placed under the cannula and contained three drops of a 1 per cent solution of pure sodium heparin (Abbott) to assure that no clotting of the lymph occurred. Lymph was collected in hourly volumes, in the majority of experiments for an eight hour period. The hourly volumes were recorded and the specimens then thoroughly mixed for five minutes. Leukocyte counts were usually made in triplicate on each specimen. In a very few instances only duplicate counts were made and in similarly few instances more than three counts were made. The counts could be checked within reasonably close limits. From the average leukocyte values per cubic millimeter and the volume it was of course possible to compute the number of white cells delivered per hour from the cannula. Smears of the lymph or its centrifuged sediment were made in every case and stained with Wright's stain. From the differential cell counts determined from such smears, the total leukocytes per hour were readily converted into absolute lymphocytes per hour. In addition to the above, one or more total and differential leukocyte counts were made on the peripheral blood during the experiment. This was done to insure that no animal used was suffering from infectious feline agranulocytosis. The hematologic studies were all made by one or another of the authors and only Bureau of Standards certified equipment was used. It was customary to maintain fluid and electrolyte balance by subcutaneous injections of isotonic saline during the experiment. Body temperature was maintained by the warmth of an electric light placed a few inches above the animal.

In normal and adrenalectomized animals receiving injections of adrenal cortical extract, two hourly collections of lymph were obtained as a baseline prior to injection. The body weight of the animals employed in this group of studies varied from 2.1 kilograms to 4.75 kilograms. Only 2 animals weighed more than 4 kilograms. No attempt was made to administer adrenal cortical extract per kilogram of body weight. However, large doses of adrenal cortical extract (Upjohn) were employed since it was desired to assure that changes, should they be found to occur, be as nearly maximal as possible. The smallest dosage given any cat, therefore, on a kilogram for kilogram basis would have been equivalent to the administration of about 145 cc. of the same preparation to a 70 kilogram man. In the normal group of 5 animals receiving hormone, 2 animals received 10 cc., 2 animals received 20 cc. and 1 animal received 25 cc. In the adrenalectomized group of 9 animals, 1 animal received 10 cc., 4 animals received 15 cc., 2 animals received 20 cc., and 2 animals received 25 cc. All injections were made subcutaneously into the tissues of one or the other rear extremities.

In the adrenalectomized group of animals, the adrenal glands were removed in two stages through flank incisions. Aseptic precautions were maintained and no studies were made on any animal developing wound infection. In order that the effects of the operative procedure would be negligible, no thoracic duct cannulations were performed until from two to twelve days after the removal of the second adrenal

gland The average interval between adrenalectomy and cannulation was five and two-thirds days In all animals used, the wound appeared healing normally or well healed During this period, animals were maintained in good condition by the following regimen Immediately after the second adrenalectomy, each animal received a single subcutaneous injection of adrenal cortical extract (Upjohn), an intramuscular injection of 5 mg (1 cc) of desoxycorticosterone in peanut oil (Percorten, Ciba) and subcutaneous isotonic salt solution No further adrenal cortical extract was given thereafter, but each day 2.5 mg (0.5 cc) of desoxycorticosterone in peanut oil was administered intramuscularly No medication was given the day of thoracic duct cannulation Desoxycorticosterone in dosage of this magnitude has been demonstrated repeatedly to have little or no effect on lymphoid tissue structure or function A solution containing 0.7 per cent sodium chloride and 0.3 per cent sodium bicarbonate was substituted for drinking water in the cages If an animal appeared dehydrated, sterile isotonic saline was administered under the skin In this manner, animals could be maintained in satisfactory shape for operation At the conclusion of the cannulation experiment, each animal was autopsied and in no case was macroscopic adrenal tissue demonstrable

The animals in these experiments were fed as usual the day before the procedure It was also customary to place a supplementary dish of milk in the cage late the afternoon before an animal was to be used No food was given the morning of the cannulation

The methods of handling the data obtained are discussed with the presentation of the data

Presentation of Data

Data are presented on 9 control animals, 5 normal animals administered adrenal cortical extract two hours after thoracic duct cannulation, and 9 bilaterally adrenalectomized animals also administered adrenal cortical extract two hours after cannulation

The data presented in tables 1, 2, and 3 indicate the lymph volume in cubic centimeters, the absolute lymphocyte counts per cubic millimeter of lymph of each specimen, and the total number of lymphocytes in each hourly collection of lymph for each cat These figures are presented for the purpose of completeness and in order that the full picture in each animal will be available for each hour after cannulation On the basis of this data, analyses for significant correlation between the treated and untreated groups of animals have been made in the following manner In all groups, the findings of the first two hours have been used as a standard of reference This standard of reference has been computed in two ways In one set of determinations the *average* values for the first two hours have been set as equal to 100 per cent In another set of determinations the values for the second hour only have been set as equal to 100 per cent The findings in each subsequent hour are then expressed as a percentage of those employed for the standard of reference This has been done in each animal, separate ratios having been determined for each of the two standards of reference mentioned before Ratios are presented for lymph volume in cubic centimeters, absolute lymphocytes per cubic millimeter, and total lymphocytes for each hourly collection period For example, if the average lymph volume in a given cat for the first two hours was 10 cc per hour and the third hour's flow was 8 cc, then the flow during the third hour was eighty per cent of the standard of reference The flow during each succeeding hour could be similarly expressed If, in the same animal, the second hour's flow was 12 cc, the flow during the third hour in terms of this standard of reference would be 66.6 per cent Ratios of absolute lymphocytes per cubic millimeter and total lymphocytes can be determined and expressed in an identical manner Separate sets of figures are presented for each stand-

ard of reference merely to determine whether any correlations could be found using either baseline. It was felt that perhaps the values obtained during the second hour might be considered more useful because the animal has had an opportunity by that time to adjust to the procedure. On the other hand the average of the first two hours

has the advantage of being a larger baseline. Both computations are therefore presented. It likewise seemed wise to seek correlations between as many different factors as possible, and therefore lymph volume, lymphocytes per cubic millimeter, and total lymphocytes were all investigated in this manner. One or both of the first two hours were used as a baseline because in no group was any animal administered adrenal cortical extract during the first two hours. In the treated groups of both normal and adrenalectomized animals each cat received adrenal cortical extract at the end of the second hour.

Having computed the ratios for each animal in these ways, it was possible to compare the animals within each group at any given hour after cannulation. Thus, for example, suppose hypothetically that in an adrenalectomized group of 3 cats,

ratios of lymph volumes during the third hour were 70, 80, and 90 per cent respectively. The mean value for such a group during the third hour would be 80 per cent of the standard of reference. Suppose that in a control group for the third hour the comparable mean is 90 per cent. The difference in the means for the two groups can be tested for significance. This can be done for each hour and for each factor to be compared. Significant differences or trends if they exist can be related to the admin-

istration of adrenal cortical extract at the end of the second hour in the treated groups, since the animals were otherwise handled in the same manner as untreated
